In these experiments, we have been repeatedly impressed with the large volume of fluid accumulating in the nose-bag during the period of experimentation. The fluid is clear as water; but it contains a considerable amount of viscous material, quite clearly mucous in character. In the last two experiments, the volume of this accumulation was measured. The lambs were twins, weighing 2·3 kgm., estimated by weight to be about 120 days gestation age. In one experiment, 37 c.c. of fluid was added to an initial volume of 30 c.c. In the second, a volume of 29·5 c.c. was added.

The conditions of the first experiment were essentially as follows: the fœtus was subjected to bilateral stellate ganglionectomy, with section of the third and fourth thoracic sympathetic post-ganglionic fibres, cannulation of the left carotid artery and bilateral adrenalectomy. A severe hæmorrhage occurred during the last procedure. As a result, during the last part of a total period lasting 1¼ hr. the fœtus was moribund, with a blood pressure of 45/21 mm. of mercury. Despite this, the volume of fluid collected was 37 c.c.

The second fœtus survived a total of 46 min. after application of the nose-bag. During this time the left carotid artery was cannulated, and adrenalectomy procedures (incomplete) and repeated temporary occlusion of either the two umbilical arteries or two umbilical veins were carried out. Upon removal of the nose-bag, a considerable quantity of clear, stringy fluid came from the mouth and nose of the fœtus; but it became mixed with blood on the table top, so it could not be recovered. Even so, the volume of fluid collected was 29·5 c.c.

At autopsy, Dr. G. W. Bartelmez examined the viscera of the fœtuses. He found no abnormal amount of fluid in the stomach or intestines.

During these experiments, the conditions of which were rather extreme, significant secretion of fluid occurred in the naso-pharynx and mouth. It was rich in mucin. If this fluid had passed normally into the amniotic sac, as it would have done had the fœtus been *in utero*, significant quantities of water, salt and protein would have been added to that fluid. It is possible that some fluid may have been swallowed, in the absence of ligation of the œsophagus, or have passed into the lungs, although this is unlikely since at no time were there respiratory movements. It seems clear, in any event, that secretions of the naso-pharynx and buccal cavities are a source of amniotic fluid in the lamb during the latter part of gestation.

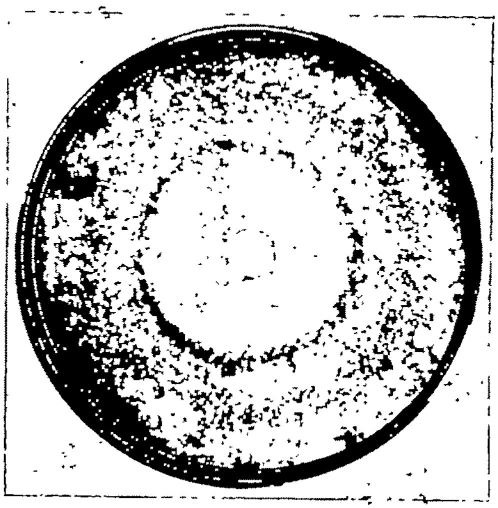
Specific Suppression by Glycine of the Phenotypic Expression of Partially Reverted Glycineless *E. coli* Mutants

THE enhancement of the phenotypic expression of delayed mutations has been reported by Witkin[1]. The purpose of the present communication is to describe the suppression by glycine of the phenotypic expression of a mutant with a partial requirement for glycine. Such strains arise by partial reversion of an *E. coli* mutant which is entirely dependent upon glycine or serine[2,3]. It can be shown on solid media (where selection phenomena are limited since the cells are spatially fixed) that the growth of a partially reverted strain, as well as mutations to increasingly independent types, is suppressed in minimal medium if the strain was previously grown in the presence of glycine.

This was shown in the following way: a minimal agar plate was spread with a suspension of the partially reverted strain, the plate dried, and a drop of a glycine solution placed in a hole made in the centre of the plate. After a day's incubation, a circular area of growth appears around the region of the glycine diffusion. By the second day, however, the cells on the glycine-free medium have grown to about the same extent as the cells which have by then depleted the plate of glycine. At the end of the second day, a circle of inhibition of growth begins in the area of previous glycine utilization. This clear, central area of the plate becomes increasingly obvious in contrast with the denser growth on the outer regions of the plate. By this time mutant colonies of more independent cell types appear over the outer portions of the plate to the extent that after about two days the new (primary) colonies almost cover the initial layer of growth—leaving the bare central area of inhibition, since mutations do not occur among the cells which had used glycine. An example of such a plate after four days incubation is shown herewith. Only secondary colonies are visible in this photograph.



Cells from various regions of the plate retain their respective characteristics when transferred to fresh minimal medium. After prolonged growth (at a very low rate) in minimal medium, it is possible for the suppressed cells to recover their potential abilities to grow at their former rate, and to mutate to increasingly independent types. The time needed for 'recovery' depends upon the extent of previous growth in the presence of glycine. The utilization of glycine only temporarily affects the heritable abilities of the cells to grow and mutate when transferred to a minimal medium; during glycine utilization and during the subsequent slow growth in minimal medium, the cells retain their potential characteristics as partially reverted bacteria. Thus the phenotypic expression of a mutant which has acquired a new ability, glycine synthesis, is suppressed by the presence of glycine prior to the growth of the mutant on a deficient medium selecting for this phenotype. In other words, glycine utilization has depressed specific biosynthetic abilities of the cell. This effect may be analogous to the depression of the ability of *E. coli* cells to synthesize methionine after growth in its presence[3,4].

Such a situation offers a mechanism, other than negative selection with respect to growth-rates, for the suppression of independent mutants in populations of dependent cells. As such, it is a phenomenon which should be considered in studies of reversion frequency. To determine the rate at which cell types arise by reversion of a completely dependent parent, it is, of course, necessary to grow the dependent cells in the presence of the growth-factor they require. When the cells are then plated to a deficient medium in order to detect independent cell types, it is possible that partially reverted cells could not express themselves, due to their previous growth in the presence of the growth-factor for which they have a partial requirement. It has been shown previously, in the case of the completely dependent glycineless mutant, that the reversion frequency apparently decreases with increasing amounts of growth prior to plating on minimal agar. This was not due to an accentuation of a lower growth-rate of the reverted as compared with the dependent type. It occurred because extensive growth in the presence of glycine has a depressing effect on the abilities of the reverted cells later to express themselves phenotypically when plated to minimal agar[5].

The phenomenon described may have implications in regard to problems of differentiation and abnormal growth, since it reveals a mechanism by which newly formed, faster-growing cells can be specifically suppressed by an excess of the metabolite required by the parental cell type. A discussion of the possible basis for this inhibition phenomenon is being given elsewhere[4].

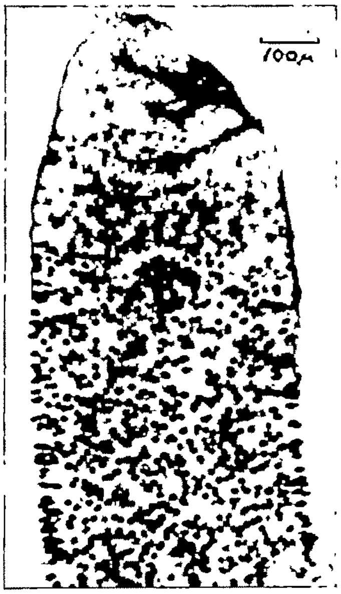
Mucus-producing Goblet Cells of the Small Intestine

IT is generally assumed that the intestinal epithelium is formed in the crypts of Lieberkühn. From this region of numerous mitoses the cells are presumed to move up towards the summit of the villi[1] from which they are shed. The average time required for the cells to pass through this phase has been calculated to be 1·57 days in the duodenum and 1·35 days in the ileum of the white rat[2]. How, when and where the goblet cells evacuate their mucus is not definitely known.

In order to answer this question I have endeavoured to make an evaluation of the intact cells. In ordinary histological sections it is impossible to account for all the mucous cells. By utilizing a method based on the preparation of intact villi and crypts by microdissection, staining the mucus of the goblet cells, and embedding in a suitably transparent medium, it is possible, however, to study the filling of intact cells with mucus and to determine their distribution in crypts and villi[3].

The experimental animals were cats, and the findings may be briefly summed up as follows: the goblet cells are most numerous near the bottom of the crypts; the number rapidly decreases towards their middle and remains nearly constant until the villus proper is reached. Here the density of goblet cells is practically constant upon the basal half, while a rapid decrease is evident towards the summit (see photomicrograph).

The cells contain small amounts of mucus near the bottom of the crypts. Then the mucus content rapidly increases and remains large all over the villus, except at the top, where the goblet cells are practically empty.



Intact villus from the small intestine of a cat. Staining: periodic acid, Schiff's method

These observations seem to indicate that the goblet cells are formed at the bottom of the crypts, where the quantity of mucus is scanty and the number of cells is large. Towards the middle of the crypts the goblet cells mature, and at the same time their number is considerably reduced. The decreasing density of the goblet cells in this region may be due to the mitotic activity of the intervening cells which push the goblet cells apart. In the cat, therefore, two generative zones exist overlapping each other only slightly: (1) deep in the crypts, there is a zone where goblet cells are generated; (2) higher up a zone of generation of columnar cells. From the crypts, the goblet cells move as components of the epithelial layer towards the summit of the villus, where they perish.

Development of Intranuclear Inclusions in Virus-diseased Cells of Lepidopterous Larvæ

FOR some time now, Dr. K. M. Smith and I have been studying, in sections for the electron and light microscopes, the role of intranuclear nets which form in insect cells infected with nuclear polyhedral viruses[1], and we are accumulating more and more data indicating that the polyhedral and previrus materials may originate in these nets. One of the biggest difficulties has been the lack of adequate cytological techniques for critically recognizing and differentiating the various intranuclear particles, and their relations to each other. Recently, Mazia *et al.*[2] published a new cytochemical method for the study of proteins using bromophenol blue as the dye, and this method, together with appropriate pretreatments of Carnoy-fixed sections, has now been used along with other methods to study the intranuclear cytology of infected cells.

Aqueous or alcoholic solutions of bromophenol blue, with or without mercuric chloride, did not stain nuclear polyhedra, in spite of the fact that they are among the most proteinaceous of all cell particles known, and though their protein is not bound to nucleic acids. This resistance to staining is paralleled by their failure to take acidic stains, for example, with Giemsa staining. After ten minutes of pretreatment in normal hydrochloric acid at 60° C., however, the polyhedra were stained intensely with bromophenol blue (with or without mercuric chloride), and perhaps more intensely than even the cross-striations of the striated muscle fibres. After the same pretreatment the polyhedra also stained, pink, with dilute Giemsa solution.

The intranuclear changes of virus-infected cells of the larvæ of several species of Lepidoptera have now been examined, and minor differences have been found between the species. Here only an outline of the main features of the sequence of intranuclear changes need be given. The nucleus of an infected cell enlarges enormously, and most of the chromatin material clumps together to form an off-central oval chromatic mass. This mass, like the chromatin material from which it is derived, stains moderately with bromophenol blue both with and without hydrochloric acid pretreatment. It is also strongly Feulgen-positive, as are many granules which develop in it. The chromatic mass later transforms into a network the non-refractile pores of which fail to stain, as also does the non-refractile nuclear sap. At about this time the nuclear mass or net reaches its maximum staining capacity with bromophenol blue, and after hydrochloric acid treatment may become as intensely stained as polyhedra. The increase of staining is evidenced not only in hydrochloric acid treated material but also in untreated material, though here the increase of coloration is not so marked. This tense staining capacity is not always afterwards maintained by the strands of the net.

At about the time of the transformation of the chromatin mass to a network, a great number of propolyhedra appear for the first time in the nucleus. They first appear outside the chromatic mass or network and not in the pores of the latter, though on occasion polyhedra may also develop within larger pores of the network and afterwards continue to develop there. The smallest of the propolyhedra observed are about 0·2–0·3 μ in diameter, and are found around the network and at the periphery of the nucleus. Like the mature polyhedra, they stain intensely with bromophenol blue after hydrochloric acid pretreatment. They grow into mature polyhedra, 1½ μ or more in diameter, by which time they pack the nucleus. It may be mentioned here that the earliest propolyhedra are smaller in diameter than the length of the mature virus rods found in the larger polyhedra. Only very rarely, and then most often in the very largest nuclei, were small propolyhedra seen in nuclei together with enlarged polyhedra 0·7 μ or more in diameter. In nuclei with enlarged polyhedra, the latter were all much the same size, for example, either all about 0·7 μ or 1 μ, etc. The evidence showed that in these species polyhedron formation is a relatively abrupt process, in which practically the entire complement of polyhedra is first formed, with each polyhedron afterwards growing in size in step with its neighbours. It is not precluded, however, that in other species or conditions the smallest propolyhedra formed may be somewhat larger than 0·2 μ in diameter, that propolyhedral formation may be a more continuous process, or that the propolyhedra arise in even more intimate connexion with the chromatic masses or nets than in the material described here.

As the polyhedra grow and begin to pack the nucleus, the nuclear net undergoes further changes. It may expand to embrace a much greater volume of the nucleus and secondarily enclose many polyhedra in its enlarged pores. At this stage pieces may become detached from the main body of the net, and a visible diffusion of Feulgen-positive material away from its remaining strands may occur, as its staining capacity for bromophenol blue also decreases. Alternatively, the pore contents of the net may transform into a mass of highly refractile non-staining globules, the Feulgen and bromophenol blue positive materials of the strands being dissipated in the process. The former process was more common in one species; the latter in another.

Several cytoplasmic polyhedroses of the midgut have also been examined with bromophenol blue techniques. In these cases, unlike what happens in the nuclear polyhedroses studied, the formation of polyhedra was a very prolonged and continuous process in any cell, those forming and maturing first arising apically, and the latter ones forming more basally. The minimal observed size of the polyhedra is here also about 0·2 μ in diameter. In one of the species examined the cytoplasmic polyhedra stained with bromophenol blue even without hydrochloric acid pretreatment. In another the hydrochloric acid pretreatment was necessary for staining, as for the nuclear polyhedroses examined. The formation of cytoplasmic polyhedra in the small basal cells of the midgut appears to be a relatively abrupt process, as with the nuclear polyhedra.

After hydrochloric acid pretreatment, the bromophenol blue technique has also been found to stain intensely the crystalline cytoplasmic inclusions of plant cells infected with tobacco mosaic virus. The method would probably prove of value also in the study of virus-diseased vertebrate cells and bacteria.

Cytological and cytochemical studies of the various polyhedroses are continuing and will be published in detail elsewhere.

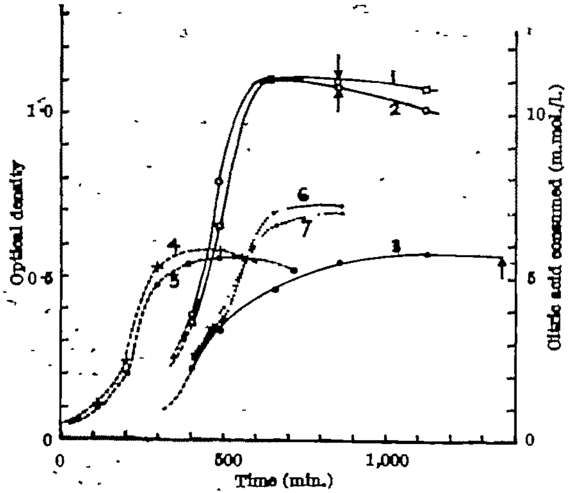
Effect of Citric Acid on the Growth of a Variant of *Bacillus subtilis*

THE role of the tricarboxylic acid cycle in the metabolism of micro-organisms has been investigated by many authors with contradictory results, and the question has been recently reviewed by Krebs[1]. This author, working with yeast, concluded that the reactions of the tricarboxylic acid cycle are primarily concerned with the supply of metabolic intermediates rather than of energy.

Experimental support for this conclusion is given by the present investigation. It is shown that citric acid, without actively participating in respiration, may be very effective in the nitrogen metabolism of



Curves 1, 2, 3. Growth curves of *B. subtilis* M_2^- at 35° on a medium containing M/10 glycerol, mineral salt (ref. 4) without ammonium salt and supplemented with: (1) □—□—□—, M/200 glutamic acid, M/200 citric acid, M/50 ammonium sulphate; (2) O—O—O, M/200 glutamic acid and M/200 citric acid; (3) ●—●—●, M/200 glutamic acid
Curves 4, 5. Growth curve of *B. subtilis* S_1^- in the same basal medium supplemented with: (4) +..+..+.., M/500 glutamic acid; (5) ●..●..●, M/500 glutamic acid and M/250 citric acid.
Curves 6, 7. Consumption of citric acid in mM/litre, in the two cultures related respectively to curves 2 and 1

a variant (M_2^-) of *B. subtilis*. We have previously shown[2] that a strain, S_1^-, can grow on glycerol (M/10) as carbon and energy source, and glutamate (M/200) as the nitrogen nutrient. The ammonium salt present in the medium is without influence and the glutamic acid is the limiting factor for the total growth; 90–100 per cent of the glutamic acid nitrogen is recovered in the bacteria at the stationary phase. With the variant M_2^-, the nitrogen balance after growth is very different (Table 1, see also graph); the total growth, expressed as bacterial nitrogen or optical density, is much smaller, the glutamate is still the limiting factor and disappears completely from the medium. The growth-rate is also much reduced, the generation-time being about 300 to 400 min. against 140 min. for the S_1^- strain. Citric acid (M/200 or M/50) enhances markedly the rate and the maximum growth of M_2^-; ammonium is without appreciable influence. On the contrary, the citric acid has a slightly inhibitory effect on a culture of S_1^-. The main difference between the S_1^- and M_2^- strains is the production of ammonium ions in the medium by the latter; this corresponds to a loss of glutamic acid, which is prevented by citric acid. Citric acid, estimated by the method of Ajl[3], is effectively utilized during growth (Table 1 and graph).

Table 1. NITROGEN BALANCE OF CULTURES OF THE *B. subtilis* STRAIN M_2^-

Additions to the medium	Nitrogen in bacteria	NH$_4^+$ in the medium after growth	Total nitrogen in the medium after growth	Nitrogen recovery	Citric acid consumption
Glut. acid 4·95	1 94	2 51	3·09	5·03	—
Glut. acid 4·95 Citric acid 20 0	3·80	0·15	1·10	4·90	6·90
Glut. acid 4·95 Citric acid 20·0 Ammon. sulph. 20 0	3·84	—	—	—	7·13

A medium containing M/ 0 glycerol and the common salts (ref. 2) without ammonium ions (final pH 6·4) is supplemented with the substances listed in the first column. All values are expressed in mM/litre. The bacteria are collected at the time indicated by the arrow in the graph. The non-ammonium nitrogen in the medium at this time may arise from a partial lysis.

In contrast with the action of citric acid on growth, very little oxidation of this compound occurs. The oxidation of glycerol is not stimulated by citric acid (Table 2). These observations show clearly that citric acid takes part in the process of synthesis, but does not essentially supply energy for the process. It is also apparent that the main action is on the nitrogen economy. As the ammonium salt has no important influence on growth in presence of citric acid, this acid is not used for assimilation of ammonium ions, but probably as an acceptor of a part of the amide group of glutamic acid.

Table 2

Substrate	Q_{O_2}	Q_{O_2} (endogenous oxidation neglected)
—	61 6	—
Glycerol	198 4	136·8
Citrate	80·4	18·8
Glycerol + citrate	206 8	145·2

Oxygen consumption in 1 hr. by 2 ml. of a suspension of washed bacteria in phosphate buffer M/20, pH 6 4. Optical density of the suspension, 2·68. Final concentration of substrate, 0 04 M.

All the members of the tricarboxylic acid cycle, or the substances which enter the cycle, act in the same way as citric acid (Table 3). The complete tricarboxylic acid cycle appears to be the basis of the main synthetic process in this micro-organism. Other experiments with the same organism[4], on transamination, support this view. This demonstration has been possible on account of the special metabolic behaviour of *B. subtilis*, in which glycerol, in spite of its role as source of energy and carbon, does not, in all probability, enter the tricarboxylic acid cycle.

Table 3

Additions to the medium	Growth
None	100
Citric acid	170
Malic acid	155
Fumaric acid	148
Pyruvic acid	136
Glucose	136
Lactic acid	136
α-Ketoglutaric acid	127
Succinic acid	126
Acetic acid	123
Ethanol acid	99
Tartaric acid	102
Butyric acid	103

Culture medium: M/10 glycerol, mineral salts and M/400 glutamic acid, at pH 6·4. All the additions are M/200, except glucose (M/400). The values of growth are the maximal values, which are reached after different times and compared with the growth without addition. taken as 100.

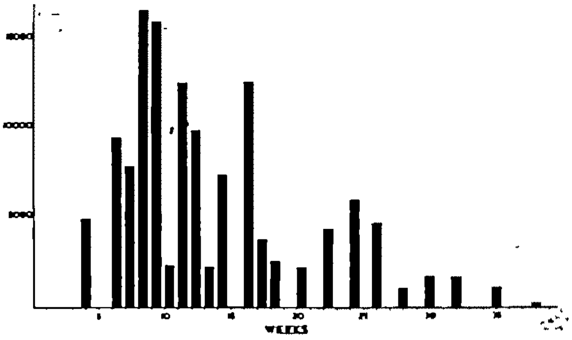
Phenomenon of Protection in Infections of *Trichostrongylus retortaeformis*

Two preceding communications[1] discussed the phenomena of host resistance in infections of *Trichostrongylus retortaeformis* in the rabbit. Two separate mechanisms were described, self-cure and the inhibition of larval development.

It now appears that there is a third mechanism of resistance which prevents infective larvæ from establishing themselves. In a series of recent experiments, rabbits were infected with *T. retortaeformis* larvæ three times a week. For the first three weeks the doses of larvæ administered increased but thereafter they remained constant. The rabbits were now receiving the equivalent of a lethal dose each week. In spite of this, however, no effect was discernible on their health or live-weight gain.

Individual members of the group were killed at regular intervals, and it was found by the estimation of their worm burdens that the number of inhibited third-stage larvæ first rose for approximately eight weeks and then fell, the rate of fall decreasing meanwhile. This progressive diminution in the numbers of inhibited larvæ was very similar to that described in an earlier letter as occurring when a large number of larvæ become established in a previously infected animal as a result of the administration of a single dose. The fæcal egg-count of the regularly infected rabbits discussed in this communication also followed a similar course and showed the same periodicity as that which was previously seen following the administration of a single dose of larvæ.



Number of inhibited larvæ recovered postmortem from regularly infected rabbits

It appears therefore that, under the conditions of these experiments, after the eighth week, although infective larvæ were still being regularly administered, both the decrease in the number of inhibited larvæ and the course of the fæcal egg-count were similar to those encountered where larvæ have been established by a single dose. It appears, therefore, that the larvæ administered after the eighth week were unable to establish themselves and that the subsequent course of the infection refers entirely to the larvæ administered before that time.

Stoll, in 1929, reported that lambs exposed to repeated infection with *Hæmonchus contortus* were able to throw off the worms and thereafter were refractory to re-infection. These phenomena he named self-cure and protection. It is suggested that the term 'protection' may correctly be used for this third mechanism of resistance to *T. retortaeformis*.

'Rabbit-Gait' in the House Mouse

In October 1952, during the classification of mice from a *fused* (*Fu*) stock, a mouse was observed with a gait closely resembling that of a rabbit. Since then, from two other matings in the same stock, four more animals behaving in a similar way have appeared. The five mice, the parents of which walk and run normally, seem to fall into two distinct classes: (*a*) those which can only move their hind legs simultaneously, and (*b*) those which move their hind legs simultaneously when running but independently when walking; in every case movement of the front legs is normal. Class (*a*) has a $Fu/+$ female and a $Fu/+$, $T/+$ (T — *brachyury*) male, and class (*b*) has two females and a male all $Fu/+$, $T/+$.

The data suggest that the condition described above is determined genetically and is closely associated with *fused*. This hypothesis is now being tested and a fuller account of the work will be published later.

Circulation in *Lacerta viridis*

USING radiological methods, Prakash[1] has recently investigated the mode of action of the heart of the lizard *Uromastix hardwicki* and has concluded that there is very considerable mixture of the blood from the two auricles in the partially divided ventricle.

At the same time we have been making a preliminary radiographic study of the heart and circulation of *Lacerta viridis*.

As is well known, in the lizards both auricles open to the dorsal side of the interventricular septum. Thus blood from the right auricle on its way to the right ventricle (cavum pulmonale) has to traverse a portion of the left ventricle. Under such conditions, it is most likely that some degree of mixture of the blood from the two auricles will take place. Again, it is well known that the right division of the ventricle is smaller than the left so that equal volumes of blood cannot possibly be pumped to general and pulmonary circulations at the same time, and we must conclude that some mixture in the ventricle is unavoidable. Nevertheless the preliminary experiments we have made lead us to the conclusion that a marked degree of separation of arterial and venous blood is achieved in *Lacerta viridis*.

In decerebrate lizards, injections of the radio-opaque medium 'thorotrast' have been made both through the posterior vena cava and through the pulmonary vein. In posterior vena cava injections the thorotrast is seen to pass through the heart into the pulmonary arteries, and in the few experiments so far made the 'dye' cannot be seen in the carotid vessels or right systemic arch. There is a slight element of doubt as to whether in one instance 'dye' can be seen in the left systemic. On the other hand, 'dye' injected into the left auricle by way of one of the pulmonary veins is clearly seen to emerge in the carotids and both systemic arches. No sign of it has been seen in the pulmonary arteries.

It is proposed to continue and extend these studies; but in the meantime it seems desirable to record that the very considerable mixture of blood in the ventricle found by Prakash[1] in *Uromastix hardwicki* is not found in *Lacerta viridis*.

Attention must also be directed to the fact that the results so far obtained tend to support the views of von Hofsten[2] concerning the nature of the blood conveyed by the left systemic arch in reptiles. Von Hofsten maintains that in Lepidosauria during ventricular systole the free edge of the interventricular septum tends to complete the division of the ventricle in such a way that the opening of the left systemic arch lies alongside that of the right in the cavum arteriosum (left ventricular cavity) and that therefore these two systemic vessels receive blood of the same degree of mixture. But in Chelonia, von Hofsten believes that the opening of the left systemic arch lies to the right of the free edge of the interventricular septum and so during systole will receive blood from the cavum pulmonale. On this latter point we can express no opinion at present; but the results outlined above lead us to believe that in *Lacerta viridis* there is no marked difference in the type of blood conveyed by left and right systemic arches.

Intersexuality in *Asellus aquaticus* L. parasitized by a Larval Acanthocephalan

Intersexes in *Asellus aquaticus* L., in which the anterior abdominal appendages are intermediate in form between the male and female condition, have been recorded from time to time and their occurrence has been reviewed by Maercks[1]. They were always females, 5–8 mm. in length. Needham[2] has pointed out that their anterior pleopods, which were never completely male in form, correspond to various stages in the normal development of the male organs.

Collections of *A. aquaticus* from two sources in Perthshire have yielded 80 individuals, approximately 1·5 per cent of the total collections, parasitized by a larval polymorphid. Of these parasitized individuals, 39 appeared to be normal males of 3–8 mm. and 13 normal females of 3·25–7 mm. The remainder, 28 individuals of 5–8·5 mm., showed various degrees of intersexuality. More than 90 per cent of those parasitized were noticeably darker than normal.

All the females and the intersexes had unexpanded oostegites typical of the immature or non-breeding female. The second pleopods of the intersexes were at different stages of development similar to those described by Needham[3] in the normal development of the male. In those individuals in which the development of the second pleopods was well advanced, first pleopods of male form were present. Where both first and second pleopods were almost completely male, copulatory styles were sometimes present. In some cases, development of the second pleopods was more advanced on one side than on the other.

Like those described by Maercks[1], these intersexes would seem to be modified females, since it is possible to arrange them in such a way that their anterior pleopods present a series similar to that seen in the normal development of the male. Further, three females and one intersex showed a change in a male direction after being brought into the laboratory. Two of these females developed first pleopods while under observation, confirming Needham's[3] assertion, on embryological grounds, that it is the first pair of pleopods which is absent in female *Asellus*.

These intersexes differed from those described by Maercks[1] in that copulatory styles were never present unless both first and second pleopods were almost completely male, whereas in his specimens copulatory styles were always present although the first pleopods might be absent and the second only slightly male. Unlike his intersexes, they have not been found carrying eggs or with expanded oostegites although collected together with many breeding females.

The fact that all the parasitized females and intersexes had immature oostegites is similar to the observations of Le Roux[4] on the state of oostegites in *Gammarus pulex* (L.) parasitized by the larvæ of the acanthocephalan *Polymorphus minutus* (Goeze). It has been shown experimentally by Le Roux[5] for *Gammarus* and by Haemmerli-Boveri[6] for *Asellus* that the development of the oostegites is correlated with ovarian activity.

Although in the present instance no intersexes have been found among more than 3,500 unparasitized *Asellus*, it is not suggested here that intersexuality only occurs in parasitized individuals. Maercks[1] sectioned his specimens so that any parasites present would have been seen.

It is hoped to carry out further work on the relationship between intersexuality and parasitization in *Asellus*.

Distribution of Copper Fungicide Deposits on Plant Surfaces

In work on spray application problems, a simple method has been devised, capable of use in the field, by which the pattern of copper fungicide deposits on treated plant surfaces may be assessed and permanently recorded. Earlier methods using paper impregnated with a suitable detecting agent are not entirely satisfactory, since deposits accumulating in depressions may not be picked up. This has been overcome by preparing an impression of the treated surface in plaster-of-Paris.

The plant surface holding the deposit is gently pressed into the calcium sulphate cream, taking care to avoid the occlusion of air. The plaster is allowed to harden for some twenty minutes, and the plant material is then carefully peeled off. The plaque, which retains the deposit, is then wetted with a 0·2 per cent aqueous solution of sodium diethyldithiocarbamate, when the imprint of the distribution of the fungicide develops. An approximate quantita-

tive assessment of distribution may be made by comparison of the intensity of coloration at different points of the plaque with that from standardized droplets of the same fungicide upon the same plant surface.

The plaster technique has also been used for lime sulphur deposits. Here the cream is made with 0·5 per cent silver nitrate solution, and, after removal of the plant material, the plaque is immersed in a fixing solution of sodium thiosulphate and potassium metabisulphite and well washed in running water. We have also adapted the thallium test described by Feigl[1] for the detection of the deposit on the plaque.

We have used the plaster method successfully to record the levels and distribution, following different treatments, of copper deposits on bean, potato, tomato and banana leaves and of lime sulphur deposits on apple leaves and fruitlets. Typical plaques are shown in Figs. 1 and 2. The technique may prove particularly useful in studying copper application problems in tropical areas where loss and redistribution of deposits by rainfall are important considerations.

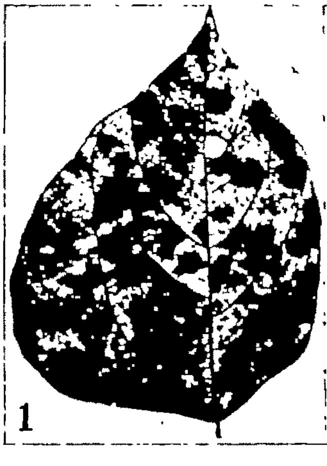
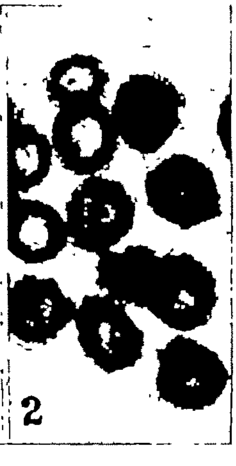
Angular Black Spot Disease of Mung Beans

Severe leaf spot disease on mung bean (*Phaseolus radiatus* L.) was observed near Banaras, India, during the months of September and October when the plants were just reaching maturity. The infection spots appeared mostly on lower leaves and could be easily mistaken on the basis of field symptoms for *Cercospora cruenta* occurring on the same host. Infection spots first appear as pale green angular spots, gradually deepening in colour, finally turning purplish-black to opaque (Fig. 1). The spots are usually 4–6 mm. × 3–6 mm., often coalescing to form patches. There was no indication of the diseased leaves showing premature drying up.

Detailed microscopic examination of the diseased parts indicated that the disease was incited by a species of *Protomycopsis*. The mycelium is inter-



1



2

cellular, septate, branched, developing numerous dark reddish-brown resting spores. Young spores are at first thin-walled, hyaline and pyriform, and turn deep brown and warty as they mature. The mature spores are reddish-brown, globose-oval, thick-walled, covered with pyramidal warts, measuring 22·5–32·5 μ (Fig. 2). Studies on germination of resting spores and other cultural studies are in progress.

As regards the identity of the pathogen, the fungus is a species of *Protomycopsis*, which is indicated by the warty nature of its exospore and other characters. *Synchytrium phaseoli* Patel, Kulkarni and Dhande was reported from Jalagaon, Bombay State, by Patel *et al.*[1], as inciting leaf spots on mung beans. A portion of the type material was examined by us through the kindness of Dr. M. K. Patel. The results suggest that the fungus reported as *S. phaseoli* is identical with the fungus found by us. The intercellular hyphæ and resting spores distributed in the spaces indicate that it bears no relation to *Synchytrium*. The name *Synchytrium phaseoli* Weston precedes *S. phaseoli* Patel *et al.*, consequently the *Protomycopsis* species under study is designated *P. patelii* Pavgi and Thirumalachar *nom. nov.* in honour of Dr. M. K. Patel, who has contributed greatly to our knowledge of Indian fungi.

A detailed account will be published elsewhere.

Preservation of the Virus of Tomato Spotted Wilt in Dried Plant Material

It is difficult to obtain accurate information about the properties of viruses which lose their infectivity *in vitro* too quickly. Tomato spotted wilt virus is one of these, and investigations on it are further limited by the fact that it is inactivated at comparatively low temperatures (35° C.). The *in vitro* life of tomato spotted wilt virus was reported by Bald and Samuel[1] to be about four hours in undiluted expressed juice held at room temperature. Subsequent work by Best and Samuel[2] and by Best[3] showed that the factors causing inactivation were the *p*H value of the juice and a tyrosinase catalysed oxidation, and that by controlling the *p*H value and redox potential of the medium[4] the virus could be maintained infective in solution for thirty-five days at 2° C.

Slow drying of infective plant tissue near the freezing point was not successful.

Transferring freshly harvested infective material to a 'deep-freeze' at − 20° C. met with partial success: strain[5] *A* survived for thirty-two days but not for seventy-four days, and strain *E* remained infective for thirty-six days but not for seventy-eight days.

The most successful method yet tried is to freeze-dry tissue and store it at a low temperature. Tomato leaflets infected with strain *A* and tissue of *N. glutinosa* infected with strain *E* were put into a deep freeze at − 20° C. as soon as they were harvested. Within two hours the leaves were removed, cut as quickly as possible into pieces about 5 mm. square and put into a flask of a freeze dryer actuated by a high-vacuum pump and suitable refrigerants. The temperature in the bulb was about − 30° C. It took about eight hours to dry 11 gm. (fresh weight) of tomato leaflets. This operation was kindly performed for us by Mr. Zwar, of the Section of Plant Physiology of the Commonwealth Scientific and Industrial Research Organization. After eight hours, all but the last traces of water were removed and the material was transferred to screw-top bottles and stored (in the presence of air) in a deep-freeze at − 20° C. After 36, 82 and 125 days of storage, portions of each sample were withdrawn suspended in buffer solution of *p*H 7·5 made 0·01 molar in respect to sodium sulphite. Inocula prepared in this way were inoculated on to plants of tomato, tobacco and *N. glutinosa* by methods described in our previous papers. After storage for thirty-six and for eighty-two days, all inoculated plants became infected with the virus. The reaction of plants inoculated 125 days after harvesting showed that both strain *A* and strain *E* of tomato spotted wilt virus had survived; but there was some evidence that the mild strain *E* is not holding out as well as strain *A*.

The tests are still in progress.

Causes of Coconut Nutfall and Gumosis

Way[1] has reported that the coreid bug *Theraptus* sp. is the cause of nutfall and gumosis of coconuts in East Africa. During more recent investigations to discover economical methods of combating this pest, it has been found that *Theraptus* sp. is only one of at least four insect pests causing either nutfall or gumosis or both. The larvæ of the weevil *Diocalandra frumenti* F. will cause both nutfall and particularly gumosis of immature nuts. Mansfield-Aders[2] noted the presence of *D. frumenti* in coconuts in Zanzibar and suggested that it might be a cause of nutfall and gumosis. *D. frumenti* thrives best in areas infested by *Theraptus* sp. and *Anoplolepis longipes* Jerd. It is preyed upon by both *Anoplolepis custodiens* Smith and *Œcophylla smaragdina* L., var. *longinoda* Latr. The larvæ of the moth *Lamoria* sp. cause considerable nutfall in palms foraged by *A. longipes* and *Pheidole* sp. by boring into and eating the bases of the young nuts. A major cause of nutfall in areas where *Theraptus* sp., *D. frumenti* and *Lamoria* sp. have been either eradicated or controlled by insecticides is the ant *Polyrhacis schistacea* Gerst., vars. *rugulosa* Mayr and *militaris* F. These ants nest both in the ground and in the palms, and feed mostly on pollen and nectar. They are so efficient at removing the nectar from flowering nuts that they remove the lining of the stigmata and prevent fertilization. In palms heavily foraged by *Polyrhacis* sp. complete loss of nuts occurs.

Theraptus sp. *D. frumenti* and the larvæ of *Lamoria* sp. are all very resistant to DDT, whether used as a wettable powder or dissolved in oils. However, the addition of coumarone resin[3] renders the same formulations highly toxic and persistent. To prevent *Pheidole* sp. foraging in palms, a 10 per cent DDT (80 per cent *para para*) with 1 per cent coumarone indene resin (grade C.469 from the British Resin Products, Ltd.) dissolved in power kerosene is effective. This spray is persistent for at least three months when used in the crowns of the palms, and for five months when applied around the trunks of the palms. It has little effect on the larger species of ants such as *Œcophylla smaragdina*, *Anoplolepis custodiens* and *Polyrhacis* sp. *Polyrhacis* sp. can be controlled by spraying the trunks with 'Dieldrex'. The addition of 1 per cent coumarone indene resin to 10 per cent 'Dieldrex' prevents it being washed off the trunks by rain and at least doubles its persistence.

Theraptus sp. has been successfully eradicated from Prison Island, which had 168 heavily infested palms, with one spraying of 3 per cent DDT plus 0·3 per cent resin. By using 'Eclipse' pneumatic sprayers, all the palms were hand-sprayed in one day. So far as is known, *Theraptus* sp. has no wild host plants; it has been found only on mangoes, guavas, cinnamon, cacao and coconuts. It feeds only on the fruits of these plants, which often fall off after developing necrotic lesions. In the laboratory it has been very successfully reared on French beans (*Vigna* sp.).

Large-scale control is now being attempted by drift-mist spraying using a 'Micron' sprayer, which in still air will throw a mist up to 70 ft.

Fuller reports on these coconut problems will be published elsewhere. I wish to thank Mr. A. K. Briant, the director of agriculture, for permission to publish this note, and Dr. W. J. Hall, of the Commonwealth Institute of Entomology, for the insect identifications.

Resistance to a Plant Disease associated with High Glucose Content of Leaf

Knight and Clouston[1], and Knight[2], in a series of papers from 1939 onwards, have worked out the genetics of the resistance of cotton to the blackarm disease (*Xanthomonas malvacearum*) and have succeeded in transferring resistance from New World to Egyptian (Sakel) types.

Clouston has found (private communication from Dr. R. L. Knight) that leaf extracts of blackarm-resistant cottons had a stronger reducing action on Fehling solution and considered that this might be associated with the mechanism of blackarm resistance.

We have confirmed this for synthesized varieties containing the blackarm resistance genes B_2 and $B_2 + B_3$, compared with their susceptible parent type. In addition, by the use of a quantitative paper-chromatography technique[3], it appears that this stronger reducing action of a water extract of the dried material may be attributed to a significantly higher glucose-level in the leaf, which is present from the cotyledonary stage onwards, in plants from different plots, sampled at different times of the day. The resistant seed contains higher sucrose and raffinose (the only two sugars found present), and possibly more oil, although this has not been sufficiently confirmed. The phosphate content, as measured colorimetrically on a 2 per cent acetic acid extract[4], is also generally, but not always, higher in the resistant leaf.

The leaf glucose-level in the susceptible plants, which is very low at the beginning of the season, appears to rise steadily with time, while that of the resistant remains consistently high. Three months from sowing, the glucose-level in the susceptible plants appears almost as high as in the resistant planted at the same time.

While no inhibition of the local strains of *Xanthomonas malvacearum* on nutrient agar has been observed here with additions of glucose up to 10 per cent w/v, one case[5] has been quoted where additions of both glucose and phosphate have inhibited growth, but only after sterilization at high temperatures.

It seems certain that resistance does not reside in the glucose itself, but in some factor which gives rise early to a high glucose content. The problem is still under investigation.

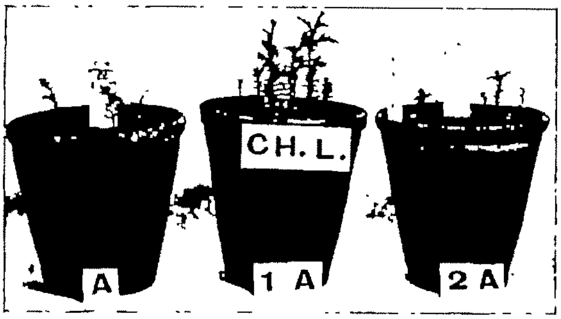
Growth Response of Tree Seedlings to Mycorrhizal Mycelia in the Absence of a Mycorrhizal Association

MYCELIUM known to produce ectotrophic mycorrhizas can stimulate the growth of an endotrophic tree species although it does not form an association with the roots. This was demonstrated in pot-culture experiments in which seedlings of Lawson cypress (*Chamaecyparis lawsoniana* Parl.) were raised in soil inoculated with *Rhizopogon luteolus* Fr.

A poor heathland soil free from the mycelium of *Rh. luteolus* and from a mycorrhizal associate of Lawson cypress was used as potting medium. Sterilized soil which one would regard as the ideal substrate for inoculation experiments did not prove suitable as it produced relatively good control plants, thus not allowing for a full demonstration of the growth response to the inoculum. Furthermore, the activity of the ectotrophic mycelium was observed to be less vigorous in the sterilized than in the unsterilized soil.

Rhizopogon luteolus was inoculated in the form of mycorrhizal roots of Scots pine. This method was used in preference to introduction of mycelium from pure culture, as results of earlier experiments had shown that mycorrhizal material was more effective



Seedlings of Lawson cypress (*Chamaecyparis lawsoniana* Parl.) in their second growing season: (*A*) control soil, not inoculated; (1*A*) soil inoculated with mycorrhizal pine roots; (2*A*) soil inoculated with non-mycorrhizal pine roots

than a mycelial inoculum. Before introduction into the soil, the mycorrhizas were surface-sterilized with mercuric chloride.

Among the various kinds of controls employed in the experiment were cultures inoculated with non-mycorrhizal roots of pine and some with fully sterilized pine mycorrhizas.

At the end of the first season of growth, marked stimulation of root and shoot development took place in the Lawson cypress cultures that had been inoculated with active mycorrhizal roots. The accompanying photograph illustrates the improvement in growth of the 'treated' plants (1*A*) as compared with absolute controls, not inoculated (*A*) and controls inoculated with non-mycorrhizal pine roots (2*A*). (No root infection was observed in the stimulated seedlings or in the control plants, confirming that the cultures had been kept free from soil contamination.)

Employing the method of root inoculation, further experiments are in progress to test and analyse the effect produced by ectotrophic mycelia on endotrophic tree species.

So far, no instance of the converse relationship, the influence of an endotrophic mycelium on an ectotrophic species, has been recorded.

Distribution of Dickite in some British Sandstones

SAMPLES of sandstone containing well-crystallized material belonging to the kaolin group of minerals have been collected and examined microscopically (by F. S.). In thin sections of the rocks the mineral appears prismatic or vermicular with pronounced transverse cleavage. The powder obtained by gently crushing the rock and sieving shows prismatic grains and hexagonal plates between 5 and 50 microns in diameter. Material having this appearance occurs in: (1) Lower Carboniferous sandstones from Anglesey and Caernarvonshire, (2) Millstone Grit from Anglesey, Staffordshire and Yorkshire, and (3) Middle Jurassic sandstones from Yorkshire. Although concentrations have been observed in cavities of fossil plants, the mineral occurs for the most part as a finely disseminated constituent of the rock, amounting to as much as 5 or 10 per cent by weight and having considerable vertical extent over wide areas.

Six specially pure separations were made for examination by X-ray diffraction methods (undertaken by G. B.). Powders from Lower Carboniferous sandstone near Bangor, Caernarvonshire, and from Millstone Grit, Bodorgan, Anglesey, both proved to be dickite with some quartz. Four separations from Yorkshire samples (Millstone Grit from Ellingstring and Middle Jurassic sandstones from the Whitby, Farndale and Bransdale districts) were all found to be dickite with some quartz and felspar.

Distribution of dickite (based on microscope examinations) in the Middle Jurassic sandstones of Yorkshire. Outcrop greatly simplified

Greenly[1] described the Anglesey occurrences as kaolinite, but this was before the division of this mineral into distinct species by X-ray methods[2]. Hemingway and Brindley[3] recorded dickite in cracks, septaria and fossil casts from the Middle Jurassic rocks of Yorkshire.

Where the clay mineral crystals are observed microscopically there is usually evidence of alteration of other minerals, for example, the progressive solution of some of the heavy minerals, particularly garnet, and the formation of one or more of the following: anatase, brookite, outgrowth on zircon, and outgrowth on tourmaline. An examination of some 250 sandstones from the Middle Jurassic of Yorkshire suggests that the clay mineral crystals are characteristic of that part of the outcrop (Fig. 1) where severe alteration of the heavy minerals has been attributed to prolonged diagenetic changes which took place while the deposits were deeply buried[4], and a similar explanation may be offered for the development and distribution of the clay mineral crystals.

More detailed accounts of the geological distribution and of the mineralogical properties of the material will, it is hoped, be published elsewhere.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Research Student (physics graduate with first- or good second-class (special) honours degree in physics) to work on ultrasonics—The Registrar, King's College, Newcastle-upon-Tyne (August 24).

Deputy (Principal Scientific Officer Grade) (with first- or second-class honours degree or equivalent in physics or chemistry, and an interest in biological problems) in the Field Trials Section of the Ministry of Supply Research Establishment, Salisbury, to design and supervise highly specialized forms of field trials—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A200/53A. (August 29).

Lecturer in Civil Engineering (with good honours degree, and at least two years practical experience)—The Registrar, The University, Nottingham (August 29).

Research Assistant (with experience of work in microbiology) in the Department of Botany—The Secretary, University College, Gower Street, London, W.C.1 (August 29)

Assistant Lecturer in the Department of Pure Mathematics—The Registrar, University College of Wales, Aberystwyth (August 31).

Assistant Lecturers in Chemistry (with qualifications in Physical Chemistry)—The Registrar, The University, Manchester 13 (August 31).

Leverhulme Research Fellowship in Engineering Production—The Registrar, The University, Edgbaston, Birmingham 15 (August 31).

Research Assistants (2), (with good honours degree in mathematics, physics or engineering, and preferably some experience in the field of aerodynamics or acoustics) in the Department of Aeronautical Engineering, to assist and initiate research on turbulence, jet noise and ground silencing devices—The Secretary and Registrar, The University, Southampton (August 31)

Principal Scientific Officer (with first- or second-class honours degree or equivalent in physics, and several years relevant postgraduate experience) at the Ministry of Supply Experimental Flying Establishment, Salisbury, to lead a section responsible for the complete design and proving of aircraft test instruments; to initiate methods of measurement of any physical quantity in test aircraft; to guide the aircraft industry in methods of maintenance and calibration of instruments used in test flying—The Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.4236/53 (September 3).

Lecturer in Bacteriology—The Secretary, The University, Edinburgh (September 5)

Lecturer in Engineering—The Secretary, The University, Aberdeen (September 5)

Senior Scientific Officer (with good honours degree in botany or agricultural botany, and research experience in genetics and/or plant breeding) and a **Scientific Officer** (with good honours degree in botany or agricultural botany) **in the Grass Breeding Section**—The Registrar, Welsh Plant Breeding Station, University College of Wales, Aberystwyth (September 5).

Graduate in Biochemistry or Chemistry (preferably of Ph.D. standard) to work on problems associated with the sprue syndrome and other nutritional disorders—Prof. A. C. Frazer, Department of Pharmacology, Medical School, Birmingham, 15 (September 12).

Assistant Lecturer (with special interests in research into child psychology) in the Department of Psychology, and a **Research Assistant** to carry out experimental work under the Professor of Psychology—The Registrar, The University, Manchester, 13 (September 15).

Feeney Chair of Metallurgy—The Registrar, The University, Edgbaston, Birmingham 15 (September 30).

McRobert Research Fellowship to undertake research relating to any disease that is generally regarded as malignant or incurable in any one of the following fields selected by the candidate and approved by the University: Bacteriology, Biology, Chemistry, Chemo-Therapy, Clinical Science, Endocrinology, Pathology or Physics—The Secretary, The University, Aberdeen (September 30).

Senior Lecturer in the Department of Psychology, University of Natal, Durban—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (September 30).

Biochemist to work on enzyme adaptation and related problems—Prof. John Yudkin, Queen Elizabeth College, Campden Hill Road, London, W.8.

Chemist (Senior Scientific Officer Grade) to lead small team engaged in the study of organic tannins (natural and synthetic) from the fundamental and technological standpoints; a **Chemist** (Senior Scientific Officer Grade) to be analyst for the Liaison Department; and a **Physics Graduate** (Scientific Officer Grade) to study the physical properties of leather—The Director of Research, The British Leather Manufacturers Research Association, Milton Park, Egham, Surrey.

Honours Graduate (with experience in use of infra-red spectrophotometer) to assist in programme of research on various substances isolated from dairy products—The Secretary, National Institute for Research in Dairying, Shinfield, Reading, quoting 53/14.

Metallurgists (with degree in Metallurgy, or A.I.M. or equivalent qualifications) in the Ministry of Supply at Aldermaston, Berks, to assist processing radio-active metals—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting F.76/53A.

Physicist or Research Engineer (with first- or second-class honours degree and research experience, preferably in textiles, plastics, or similar materials) to carry out basic research on the mechanical properties of fabrics—The Director of Research, The British Cotton Industry Research Association, Shirley Institute, Didsbury, Manchester 20.

Professor of Geography—Dr. A. A. Duri, Dean, College of Arts and Science, Baghdad, Iraq.

Senior Experimental Officer (with at least H.S.C. (Science) or equivalent, but degree or H.N.C. may be an advantage) in the Electronics Division of the Atomic Energy Research Establishment, Harwell, to take charge of small section responsible for design and construction of small electro-mechanical mechanisms—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting D.302/53A.

Senior Scientific Officer or Scientific Officer (with first- or second-class honours degree in physical chemistry and postgraduate experience in physico-chemical research, and preferably with specialized knowledge in the field of high polymers) in the Department of Scientific and Industrial Research, Chemical Research Laboratory, Teddington—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting F.368/53A.

BIOLOGICAL SCIENCES IN BRITISH SCHOOLS

IN 1928 the British Association for the Advancement of Science published a report on the place of animal biology in the school curriculum. Since then, substantial changes have occurred in British education in general and in scientific education in particular. In view of these changes, Section K (Botany) of the Association suggested in 1949 that an inquiry into the present position in school biology would be desirable. As a result, the Council of the Association set up a committee to consider the position of biology and rural science in the school curriculum; its report has recently been published[*].

Since biological science is changing rapidly, and since the trends in school practice are varied and important, the committee felt that its report must be considered as one of a series to be produced over the years.

The committee was made up of four professors of botany, a professor of horticulture, two university lecturers in zoology, a headmaster and a biology master from grammar schools, an inspector of schools and the directors of two professional biological associations. Since the inquiry was concerned with schools, it is difficult to understand why the committee did not include greater school representation; it is even more difficult to understand why no primary or secondary modern school representatives were invited to join the committee and why at least one representative of a girls' school was not asked to participate in its discussions. Apparently no consultation with Section L (Education) of the Association took place before the committee was constituted; its deliberations might have been more fruitful if such consultation had occurred. Nor is it easy to understand why the British Social Biology Council, an organization which, for many years, has devoted its attention to the teaching of biology in schools, was not consulted.

The report of the committee was based upon the assumption that factual information must first be obtained from as many sources as possible and that it should be presented together with constructive and realistic recommendations. By questionnaires and other means, inquiries were made in schools, in teacher-training colleges, field-study centres, and university departments of education and of the biological sciences. The inquiries have covered the whole of England, Northern Ireland, Scotland and Wales.

In primary schools, the majority devote some periods to simple biological work which often consists of observations of natural phenomena, and the time so devoted appears to bear a reasonable ratio to other subjects at this stage. Effective biological teaching would appear to exist in many schools not professing to teach biology, the appropriate subject-matter appearing in the curriculum as nature study, natural history or health education. Little evidence has been obtained of the purposeful linking of biological teaching with other subjects, such as geography, or of its evaluation in relation to rural science.

---

[*] *The Advancement of Science*, 10, No. 37 (1953).

In contrast to such class-room activities in primary schools, field-work appears to occupy a very small proportion of the time allocated to biological studies. Nature walks form a part of many schemes. Many schools keep rabbits, poultry, bees and other 'domestic' animals, and school gardens, tended by the pupils themselves, provide a useful source of practical work. In only a few schools do out-of-school clubs exist in which pupils can develop hobbies having a biological bias.

Very few primary schools possess special accommodation for biology, and simple equipment for much-needed and valuable experimental work is also lacking. Only a few of the teachers responsible for biological teaching in primary schools have taken biology as a training college subject; the majority have no such special qualification. In too many instances, less effective work in the biological field is undertaken in primary schools than is both possible and desirable.

From these observations, the committee recommends that, in primary schools, teachers should stress the relationship of biological studies to problems of everyday life and should so adjust their teaching as to make more clear than is now usual such inter-relationships, and particularly the co-ordination of biological topics with such subjects as geography and hygiene. Outdoor work by pupils should be encouraged, and heads of schools should foster suitable clubs, such as natural history societies and young farmers' clubs. Heads of schools should facilitate the work of their staffs by granting some relief for the preparation of practical studies and outdoor work. Those who teach biological subjects should be encouraged to attend suitable refresher courses to improve and extend their knowledge.

In secondary modern schools there is a great shortage of well-qualified biology teachers and, as the committee observes, there appears to be little hope of improvement in the near future. The recommendation, therefore, that all courses in science in secondary modern and secondary technical schools should include biology and that biology should be taught to both boys and girls appears to be compounded of hope rather than conviction. The other recommendations for secondary modern schools follow along the same lines as those put forward on behalf of primary schools.

The main part of the report is concerned with secondary grammar schools, and here the committee treads ground which appears to be more familiar to it. In these schools many complaints were aired Biology teaching is too much confined to text-book studies with a consequent neglect of the living organism studied as an entity and a too common substitution of preserved specimens and morphological details for vital studies. In both urban and rural schools this too close attention to text-book studies has resulted in neglect of field-work even to the extent that students are entirely ignorant of common plant and animal names; few students know how to obtain these names for themselves.

During the past forty years, marked changes have taken place in the pattern of biology teaching. Since the First World War, the number of secondary grammar school pupils studying some form of biology at school certificate level has increased about seven times for an increase in the total number of candidates of only about three times. During this period the increased emphasis on general biology has resulted in more balanced courses than those which were almost exclusively botanical. At the higher school certificate level the increase in the number of biology candidates has reached seventy times that of 1918. More girls than boys study biology in secondary grammar schools; the higher proportion of girls taking biology in school certificate is partly due to the fact that fewer girls' schools teach chemistry and physics.

Several reasons are given for the small proportion of boys studying biological subjects. The opportunities offered by industry to chemists and physicists, for example, tend to divert students to these sciences. At higher school certificate level the ratio of girls to boys taking biological subjects is approximately unity, however; the increase in numbers of boys is partly due to those hoping to gain exemption from pre-medical university examinations by passing at the higher level.

Probably the most serious statement reported by the committee is that dealing with trends and standards in secondary grammar schools. While it is almost impossible to determine accurately changes in the absolute standard of teaching and the average ability and performance of students, there seems little doubt that both the quality and the quantity of biology teachers has rapidly deteriorated of recent years. Meanwhile, the total number of pupils in secondary grammar schools has increased. These increased numbers have resulted in dilution with mediocre students who must inevitably reduce the standards over the whole country, even though examination statistics give no evidence of this. During 1946–50 the percentage of awards in public examinations shows no change, and it is difficult to resist the conclusion that an arbitrary statistical adjustment is being made.

If, as the committee believes, the average quality of secondary grammar school pupils is declining as numbers increase, this procedure means an automatic fall in examination standards. Some examining boards confirm the effect of dilution and the deterioration of the quality of teaching. The committee recommends that an attempt should be made to obtain estimates and maintain records of absolute standards of performance in all external school examinations in order that trends may be revealed, the more so as trends in both numbers and standards may have been considerably affected by the introduction of the general certificate of education. It is also suggested that, if any medical school exempts students from any part of the statutory pre-medical examination in science before admission, passes at the advance level in physics, chemistry and biology of any recognized examining body should suffice for such exemption.

A useful section of the report is that dealing in some detail with the teaching of field-work, horticulture and rural science in schools. One of the most valuable suggestions is that biology should rank as a subject for third-year courses of study at training colleges, with attendance at residential field-centres included as a vital part of the syllabus. It is also suggested that, wherever possible, practical field-work should be an integral part of the curriculum throughout the school; sixth forms (especially of schools in urban areas) should attend at least one week's course at a residential field-centre during the year. This, like a number of the committee's suggestions, is scarcely realistic, and greater emphasis might have been placed on the value of field-work initiated and carried out by the pupil's own teacher. To be fully effective, field-work should be carried out continuously throughout the year and in an environment not only with which the pupil is familiar but also in which he is likely to remain for some time so that his interest may be continuously stimulated and encouraged.

In a section on the supply of biology teachers in schools, the committee notes with some concern a report which stated that during 1948–49 only 38 per cent of vacancies in biology were filled satisfactorily. The same source provides evidence that the quality of the staff is also declining. It would appear that about fifteen grammar schools each year are dropping biology, while almost fifty more schools are employing teachers having no university biological training. The estimate by the Hankey Committee that, by 1954, a surplus of biology graduates may be expected even after teaching requirements have been met is strongly contested by the committee, which questions the validity of the various criteria on which the estimate is based.

The report also discusses the supply and remuneration of laboratory assistants in schools, and gives some useful hints on methods of teaching biology in schools. This section contains little new and is mainly a restatement of principles already well known to teachers of biology and other subjects. Here new ground might have been broken if the committee had devoted some time to the teaching of biology to the rapidly increasing number of students who are being given time off from their everyday work in industry and commerce to attend general educational classes.

There is a great danger that this important report may be put on one side. The frequent pleas that local education authorities should spend money in sending teachers and students on courses, employ more teachers and laboratory assistants and provide more and better equipment will be unavailing unless they carry the conviction that these proposals really are most desirable and necessary in the building up not only of scholarship but also of character among British citizens. Unfortunately, the form and presentation of the report is much too stereotyped. It would have carried greater weight with government and local education authorities if it had been written with more force and conviction—as if the committee really believed, for example, that a greater extension of biological knowledge has something to contribute to the promotion of happiness among human beings by helping to dispel fads and superstitions which rule the lives of the majority of men and women and which rightfully belong to a period of history long before the advent of modern science. The committee might well have referred to the £47 million spent on drugs in Britain under the National Health Service last year and the savings that could be effected with the spread of biological knowledge; most of these drugs were taken by people, many of them belonging to the so-called educated classes, who have little knowledge of the working of their own bodies. The amount of money spent each year on prepared and patented foods might also have been mentioned.

This is an age of reports, and, in days of educational economy, the only ones which pass beyond the files are those which are alive with truths so challenging that action becomes desirable and compulsive. Others turn out to be mere intellectual exercises.

A GEOPHYSICAL MIXTURE

Advances in Geophysics

Edited by H. E. Landsberg. Vol. 1. Pp. xi+362. (New York: Academic Press, Inc.; London: Academic Books, Ltd., 1952.) 7.80 dollars.

THIS volume contains eight articles covering a wide range of geophysical topics. The first two are on the automatic processing of data and on new statistical techniques; there follow a review of the general circulation of the atmosphere and two articles on the upper atmosphere. The remaining three articles are on estuarine hydrography, the earth's gravitational field and aeromagnetic surveying.

It is clear that in such a wide selection of topics almost everyone will find something to interest them; but it is perhaps not equally clear that many people will be interested in a sufficient proportion of the contents to pay 7.80 dollars for the volume. Some of the contributors seem not to have had a very firm view of the audience for which they were writing. For example, the first seventeen pages of Woollard's article on gravity contains material which can be found in any text-book, while the remaining twelve pages are devoted largely to tables concerning the values of gravity at national base stations. Woollard's work that is here summarized is of the greatest interest and importance for geodesy and geophysics; but it seems doubtful if a review article is the best place for the detailed tables, particularly when it is coupled to the rather elementary introductory matter. It is perhaps worth mentioning that Table 5 appears to ascribe large errors to the early measurements at Dehra Dun by Lenox-Conyngham and by Hecker; in fact, their results agree excellently with the modern determinations quoted later in the article.

The article on aeromagnetic surveying is remarkable in giving specimens of actual surveys of which there are few published examples. It also gives an estimate of the cost of the work as 10 dollars per flight-mile without Shoran or 20 dollars per mile with Shoran, and estimates that 7,000–10,000 miles can be worked per month. A large aeromagnetic survey is clearly not to be undertaken lightly.

The first of the meteorological articles is an account of the general circulation of the atmosphere by B. Bolin. This gives a compact account of the present state of the subject, including very clear diagrams illustrating the form and seasonal movement of the stream lines. The second meteorological article is an account by F. L. Whipple of the exploration of the upper atmosphere by the observation of meteors. This is a most welcome summary of a rapidly developing subject by one who has been responsible for many of the recent developments. It includes a fine photograph of the new super-Schmidt meteor camera that Harvard College Observatory is operating in New Mexico. The remaining meteorological article is a discussion of some unsolved problems of the high atmosphere by N. C. Gerson.

The statistical article by A. Court is mainly concerned with the frequency of occurrence of extreme values of a variable. This is often of considerable importance in such problems as the design of structures to resist wind or earthquakes and in agricultural planning.

The article by J. C. Bellamy on the automatic processing of data discusses recent developments in digital and analogue data-handling equipment and the methods available for the visual presentation of large quantities of information.

The article on estuarine hydrology by D. W. Pritchard deals mainly with the equations of motion of the water.

As a whole, the book contains much information that is not easily available, and should help to stimulate interest in many of the important matters that it discusses. E. C. Bullard

RANDOM CHOICE IN THE CHEMOTHERAPY OF TUBERCULOSIS

The Bacteriostatic Activity of 3500 Organic Compounds for *Mycobacterium tuberculosis* var. *hominis*

By Guy P. Youmans, Leonard Doub, and Anne S. Youmans. (Chemical–Biological Coordination Center, Review No. 4.) Pp. v+713. (Washington, D.C.: National Research Council, 1953.) 5 dollars.

Prof. and Mrs. G. P. Youmans and Mr. Leonard Doub are well known for their work on the chemotherapy of tuberculosis, and one looked forward with interest to reading the results of their collaborative efforts. As stated in the foreword, the present volume describes the techniques used in the *in vitro* and *in vivo* screening of three thousand five hundred compounds for their action against the tubercle bacillus, together with the results of these tests. The positive results as embodied in this volume may not unfairly be described as meagre. However, as one of the main reasons for their publication was that it might obviate unnecessary testing of the same compounds by other investigators, one must record one's appreciation of the enlightened action of the firm of Parke, Davis and Co. The work recorded here involved heavy expenditure in money and energy, and one hopes that the example of Parke, Davis and Co. in publishing unsuccessful results may be followed by other commercial firms in this and other fields. The book contains a brief introduction, followed by chapters on, respectively, rationale for the *in vitro* and *in vivo* screening programme, experimental methods, and discussion of selected data in relation to chemical structure. The fourth and fifth chapters embody the results of tests in mice and in the test-tube, respectively, the latter chapter occupying six hundred pages and containing also a formula and an alphabetical index. The printing is clear and accurate, and structural formulæ are set out with an impressive lack of restraint in regard to space.

The aim of an investigation, such as is described in this volume, is, simply stated: to discover or invent a chemical remedy which will eradicate, completely, virulent tubercle bacilli from human tissues without causing injury to the host cells. The natural approach for the chemist would be to design or select molecules likely to become involved in the bacillary metabolism. As the authors point out, our present limited knowledge of the metabolism of the tubercle bacillus does not lend much encouragement to this line of attack. They accordingly believe that the only method that offers promise of early success is random screening, and they do not hesitate to claim that there should be no basis for selection of compounds other than availability. The sentence—"The random selection of compounds to be tested should be adhered to as strictly as possible"—has a kind of lunatic flavour about it.

Finding *the* chemotherapeutic agent for tuberculosis is a difficult problem, but it will scarcely help the search to throw reason to the winds. There are known nowadays a number of widely different types of molecule of synthetic and natural origin which exert a considerable suppressive effect on the tuberculous process in man and in animals. This knowledge provides a rational starting-point for 'structural tailoring' which may lead to the production of substances of greater activity and lower toxicity. Alternatively, an intensive study of the mechanism by which any one of these substances interferes with the metabolism of the bacillus may provide an important clue which would guide further synthesis. This will be a difficult but perhaps not unrewarding investigation. If a greater proportion of the resources, which have been used by commercial firms in screening potential antitubercular substances, were diverted to the study of the chemistry and biochemistry of *Myco. tuberculosis*, progress would be eventually more rapid.

Chapter 1 gives a full description of the *in vitro* testing routine, and it is surprising to find American workers placing such reliance upon it. Compounds are tested in Proskauer and Beck's synthetic medium, and the results are used to correlate chemical structure with bacteriostatic activity. Some parallel tests are carried out in the same medium enriched by 10 per cent beef serum. This makes possible the elimination of a large proportion of compounds showing high activity in synthetic media, an activity which is considerably reduced by serum proteins. The authors point out that the reduction of "bacteriostatic activity may at times be more a function of the stimulation of growth than inactivation of the agent by combination". It is worth remembering also that "stimulation of growth" may be due to some extent to altered metabolism of the bacillus in the presence of serum proteins which would render the chemical agent innocuous. The views expressed on the conduct of tests in laboratory animals and the limited deductions which can be drawn from these experiments are eminently sensible.

Of the three thousand five hundred organic compounds tabulated, only 184 were tested in experimental murine tuberculosis and, in all, eleven were shown to exert a suppressive effect. Included in these eleven active compounds are streptomycin, viomycin, chloromycetin, *p*-aminosalicylic acid, 4,4′-diaminodiphenyl sulphone, nicotinamide and three thiosemicarbazones. Since the discovery of activity in these compounds by various workers was attained by following a lead, however slender, the heroic empiricism of the method of random selection does not inspire confidence. The *in vitro* table records the minimum concentration (mgm. per 100 cc.) which causes complete inhibition of growth for fourteen days of the *H37Rv* strain of *Myco. tuberculosis*. For the most part, the test in serum-enriched media "was run at the arbitrary compound level of 10 mg.%". This procedure very much reduces the value of the data, since it is highly important to find out the minimum concentration of the chemical agent which will inhibit growth in this medium. Furthermore, the extent to which the minimum inhibitory concentration measured in a synthetic medium is increased by the presence of serum is a very valuable indication of the probable activity of the agent *in vivo*.

One hopes that these criticisms will not seem ungracious and that in subsequent reports the maximum information will be extracted from the experimental work. VINCENT C. BARRY

ABELIAN MODULAR FUNCTIONS

Funzioni Abeliane Modulari

Lezioni raccolte dal Dott. Mario Rosati. Per Fabio Conforto. Vol. 1: Preliminari e parte gruppale; geometria simplettica. Pp. 454. (Roma: Edizioni Universitarie Docet, 1951.) 3900 lire.

ABELIAN modular functions are functions analogous to the elliptic modular function $J(\omega)$, but involving a complex matrix variable instead of a single complex variable. Such functions stand in a similar relation to the Abelian functions (meromorphic $2p$-periodic functions in p complex variables) as $J(\omega)$ does to the elliptic functions.

The first volume of the present work begins with a short discussion of the elliptic case, and an excourse on matrices. Then the Riemann matrices of Abelian functions (that is, the matrices formed by the period vectors of such functions) are studied and connected with the classification into distinct fields of Abelian functions. Every Riemann matrix is reduced to a normal form involving $p - 1$ integers and $p(p + 1)/2$ complex parameters subject to certain inequality conditions. The real and imaginary parts of these parameters are interpreted as co-ordinates in a $p(p + 1)$-dimensional space; the inequalities determine then a region R in this space which, in the elliptic case $p = 1$, is the upper complex half-plane. From the reduction of the Riemann matrices one is immediately led to the simplectic group, on one hand, and to the infinitely many distinct modular groups contained in it, on the other hand. Both types of groups are isomorphic to groups of transformations of R into itself. In particular, the simplectic group generalizes the well-known group of fractional linear transformations of the upper complex half-plane into itself, while the modular groups generalize the classical elliptic modular group.

The author studies the simplectic group in great detail and deals especially with its geometric properties. These results are finally applied to the modular groups, which are shown to be discontinuous in R and to possess fundamental regions derivable from the reduction theory of quadratic forms.

A great deal of the material of this book is due to C. L. Siegel, and the author follows his example in using matrix notation. This gives the theory a particularly elegant form and makes this one of the best books published in recent years on any subject in advanced mathematics. The print is a photographic reproduction of a handwritten manuscript and suffers a little from the drawbacks of such a method. Fortunately the calligraphy is excellent.

K. MAHLER

PROTOZOOLOGY

Traité de Zoologie

Anatomie, systématique, biologie. Publié sous la direction de Prof. Pierre-P. Grassé. Tome 1: Protozoaires; rhizopodes, actinopodes, sporozoaires, cnidosporidies, Fascicule 2. Pp. ix+1160. (Paris: Masson et Cie., 1953.) 9,935 francs.

THE great and courageous enterprise of Prof. Pierre-P. Grassé's "Zoological Treatise" has been carried another important step forward. As the story of the Protozoa unfolds in this second part of the first volume, one cannot help being impressed by the magnitude of the task undertaken by Prof. Grassé and his team. To the imposing series of volumes already doing their well-appreciated duty, yet another one has been added, and it may at once be gratefully acknowledged that it is as worthy in succession as it is full of promise for the future.

The Rhizopoda, Actinopoda, Sporozoa and Cnidosporidia are dealt with by a team of authors recruited from a variety of seats of learning in France and French North Africa. The contributors are M. Caullery, E. Chatton, G. Deflandre, P.-P. Grassé, A. Hollande, J. le Calvez, J. Pavillard, R. Poisson and G. Trégouboff. The contribution by E. Chatton is posthumous, and has been edited and supplemented by Prof. Grassé.

The present volume contains more than a thousand pages of text illustrated by 833 text figures and two coloured plates. The high quality of the line drawings and plates and of most of the photomicrographs are a credit to authors and printers alike. Among the illustrations are encountered a good number of old friends that have become classics. One would deplore their absence. Many have been redrawn, and this rejuvenation materially adds to their usefulness. The general standard of lettering and legends is high, and data concerning magnifications are a very welcome asset to quite a number of the illustrations. One would wish they were present in all. A good subject-matter index of fifty pages and a list of contents are appended. There is also a list of errata and addenda.

The wide range of protozoology covered in this volume makes a detailed scrutiny of its academic merits and its up-to-dateness well-nigh impossible. A considerable proportion of the forms described in this part of the work are parasites, and this extends the sphere of its usefulness beyond the confines of academic zoology into the realms of applied biology and medicine. Thus, a considerable body of recent research claims a place in a work of this type. A survey of the lists of references is reassuring. For example, of the 169 references on the Hemosporidia, 82 are dated from 1940 onwards. However, the authors have not yielded to the temptation to weight the volume unduly on the applied side of the subject. The chapter on malaria, for example, is concise and, although it contains a modicum of information on anti-malarial drugs and on the vectors and their control, it does not disrupt the balance and continuity of the zoological approach.

In general, the treatment of the various groups is well balanced, half of the volume being devoted to the Rhizopoda and Actinopoda, and the remaining half to the Sporozoa and Cnidosporidia. A chapter on the cytology of the Acantharia and Radiolaria is presented as an addendum. It calls on recent results of work by A. Hollande and M. Enjumet to provide a means of supplementing the treatment of problematic questions concerning the interpretation of cell structures and life-cycles in these two groups. This is just one of the examples of the care with which the authors are attempting to minimize the risk of early obsolescence which so often detracts from the value of works of this nature and scope. Style and presentation are lucid throughout, and should not present any undue difficulty to the English-speaking reader. Zoologists the world over owe a great debt of gratitude to their French colleagues for a truly indispensable book.

Otto Lowenstein

THE COUNTRY NATURALIST

Birds of the Field
By James Fisher.

Butterflies of the Wood
By S. and E. M. Beaufoy.

Flowers of the Wood
By F. M. Day,

Birds of Town and Village
By R. S. R. Fitter.

(The Country Naturalist Books.) Pp. 36+32 plates each vol. (London: William Collins, Sons and Co., Ltd.) 3*s*. 6*d*. net each.

MESSRS. COLLINS, whose "New Naturalist" series of books made a special niche for themselves both in book production and in the literature of natural history, are now issuing a new series under the general title "The Country Naturalist", which one presumes can be looked upon as a shortened and cheaper form of the "New Naturalist".

James Fisher, one of the editors of the "New Naturalist" series, is the editor of this new series, so both lay and professional naturalists can rest assured that the new venture is being well looked after and that the best possible author for each topic will be selected.

The objective of these new books is to present a well-illustrated and popular introduction of each topic to non-professional readers; though it is difficult to imagine the informed field naturalist and certainly the biologist not finding much of value and interest in each book.

The method of approach is ideal for the readers whom the editor has in mind. As he points out in his introduction, Great Britain, with its varied geology and climate, presents an intricate patchwork of woods, fields, moors, mountains, towns and rivers, with a margin of sea-coast of comparatively great length and complexity. Since each of these types of country supports its own peculiar communities of plants and animals, the obvious way to approach the study of our flora and fauna (especially from the initial point of view of identification) is through these divisions; though no doubt the various authors will realize that there is much overlapping in Nature and therefore will not confine themselves too rigidly to organisms specially adapted to, and therefore found exclusively in, the selected area. Judging from the first four books, there is to be no risk of this.

James Fisher starts the series himself with "Birds of the Field". He begins by explaining his method of selection with which no one can disagree, and then he plunges straight into his descriptions of birds to be found, classifying them in their accepted families such as those of the crow, starling, weaver, etc.—fourteen in all. The text is just what one has learned to expect from Fisher's pen—descriptions by a well-known expert and well-trained observational ornithologist who fortunately has the rare gift of analysis and interpretation which the untrained mind can not only grasp but also finds fascinating. All the thirty-two full-page plates are photographs, mostly illustrating one species in its natural surroundings, occasionally two. Sixteen are delightful colour-photographs. All the photographs have been taken by well-known colour-photographers.

S. and E. M. Beaufoy were a good choice for "Butterflies of the Wood". Their method of approach is similar to that of Fisher's. Again there are thirty-two plates of illustrations; but here it is possible to present twenty colour-photographs and eighty-one photographs in black-and-white.

F. M. Day's "Flowers of the Wood" is in the same vein, though here the introduction is longer, taking the form of an excellent essay on British woods. Well-known flower photographers have contributed seventeen colour- and nineteen black-and-white photographs which make up the thirty-two plates.

Finally, none other than R. S. R. Fitter, who charmed thousands of readers with his "London's Natural History" and also wrote the "Pocket Guide to British Birds", has contributed "Birds of Town and Village" to the series. His methods of dealing with his topic are similar to those of Fisher and the result is equally as good. His text is illuminated by thirty-two plates carrying twenty colour- and twenty-two black-and-white photographs.

In none of these books is the text confused with unnecessary technical terms or scientific names. In each case, however, a classified list of scientific names, following the most recently accepted rules for zoological and botanical nomenclature, is appended.

We note that among other books in preparation are "Flowers of the Seaside" by Ian Hepburn and "Birds of the Seaside" by James Fisher, and many more are on the way. This is good news, because here is an excellent series. James Fisher the editor, all the authors, and Collins the publishers are not only to be congratulated but also thanked for making available to everybody such books of convenient pocket size and at a price that anyone can afford.

Studies in Logic and Probability

By George Boole. Pp. 500. (London: Watts and Co., Ltd., 1952.) 25s. net.

If we accept the point of view of such eminent authorities as, for example, Whitehead and Russell that mathematics has its very roots in the principles of logic, even down to the most formalistic levels, it is not surprising that the attempt should have been made and continued to reinforce the somewhat open structure of probability theory by the application of the indisputably rigid rules of logic. Indeed, there arises a peculiar philosophical satisfaction from the display of the conjunction of the unassailably true laws of logic and of statements of something which one would ordinarily say is 'only probable'. True, the degree of being 'only probable' in the general conversational sense has been refined to a high degree of near certainty by the mathematics of the subject, but, even so, the essential uncertainty character inherent in all 'probability' remains.

The present volume applies the rules of both formal and symbolic logic to the study of mathematical probability theory, and it consists of the author's miscellaneous writings on logical subjects and his papers on related questions of probability. The period embraced by the papers is from 1847 to 1862, the latter year antedating the author's death by but two years. The book is a companion volume to "The Laws of Thought", which was first published in 1854 and reprinted in 1916 and 1951.

During recent years there has been a recrudescence of interest in applied logic and in Boolean algebra, notably perhaps in the industrial field, in connexion with the design of electrical switching circuits. This book should be welcomed by workers in that branch of endeavour as well as by those to whom it will appeal by its title subjects. S. A. S.

General Network Analysis

By Prof. Wilbur R. LePage and Prof. Samuel Seely. (McGraw-Hill Electrical and Electronic Engineering Series.) Pp. vii+516. (London: McGraw-Hill Publishing Co., Ltd., 1952.) 68s.

This book gives a general and unified treatment of networks (electrical circuits), suitable for advanced work in either power or communications. There is also some filter-design theory. Each topic is developed from the fundamental principles, but it is assumed that the reader has already taken an elementary course in the subject. The first chapter explains the use of complex numbers. The second and third give a general treatment of networks, based on Kirchhoff's laws, and using determinants, a knowledge of which is assumed. Series and parallel circuits are considered simultaneously, and stress is laid on the duality between junction and loop analyses. Some of the terms are new—for example, copedance and comittance. The fourth chapter, based on Ampère's and Faraday's laws, introduces magnetic coupling and forms a link between the points of view of communication and power engineers. Chapters 5, 6 and 7 apply the general theory to networks restricted in some way—for example, four-terminal, lumped or selective. Matrices are defined and explained before being applied. In Chapter 8 previous results are extended to polyphase systems, using the method of symmetrical components. The remaining six chapters discuss respectively circuits with distributive properties, impedance and admittance charts used in the design of transmission lines, Fourier series, transients in linear systems, the Fourier integral, and the Laplace integral applied in the operational calculus. The book concludes with a bibliography, two mathematical appendixes, but without the answers to the numerous examples for solution at the end of each chapter. It is a pity that the very high price may restrict the use of this interesting treatise. H. T. H. Piaggio

Elements of the Topology of Plane Sets of Points

By Prof. M. H. A. Newman. Second edition. Pp. vii+214. (Cambridge: At the University Press, 1951.) 27s. 6d. net.

The first edition of this book has for long been regarded as a standard introduction to the ideas and methods of topology.

In the second edition, substantial changes have been made, resulting in the rearrangement of the contents of Part 2 of the first edition. Thus Chapter 6 gives the 'homology' theory of simply- and multiply-connected domains, and Chapter 7 the 'homotopy' theory (paths and their deformations). The author states in the preface: "The treatment of homology on a grating has been modified so as to make clear the distinction between 'chains' and their point-set loci. The sections on boundary elements of domains, and on the connectivity of certain kinds of closed sets, have been omitted, and their place taken by a section on the orientation of plane curves. A number of topics, such as the properties of vector spaces of infinite dimension, the Jacobian theorems on implicit functions, and the Cauchy integral theorem (with one or more boundary curves), are treated as examples".

Part 1 remains practically the same as in the first edition, and consists of chapters on sets, closed and open sets in metric spaces, homœomorphism and continuous mappings, connexion, and separation theorems. The second edition is likely to become even more a standard work than the first edition.

R. G. Cooke

A Sanctuary Planted

By Walter J. C. Murray. Pp. 191+33 plates. (London: Phoenix House, Ltd., 1953.) 15s. net.

This book describes the evolution of a scheme, perhaps one should say a dream, by which a plot of unexciting ground was turned into a little Paradise, a sanctuary for birds, beasts and insects, where lovely wild flowers could flourish and shy birds could come to breed. The busy schoolmaster found joy and relaxation in his planting and planning, he learnt of the things attractive to birds, what trees and shrubs they prefer and of the necessity for food, shelter and water, particularly the last. He tells of his struggles and successes, of the Sanctuary through the changing seasons, of sunshine and storm, of its plants, insects, birds and animals and of its many delights. His experiences will aid others likewise bent on converting a waste corner of the garden, some old shrubbery or other piece of land into a place of delight. The author gives at the end of his book a helpful list of trees and shrubs that he has tried, with notes on flowering time and purpose. His photographic illustrations, from the colour snapshot on the jacket to the many black-and-white pictures in the book, are testimony to his skill with a camera. The photographs of different birds, including the bullfinch and the chaffinch bathing, are particularly good, and so are the butterfly pictures.

Frances Pitt

GEORGE BERKELEY, 1685–1753

THIS bicentenary year of Bishop Berkeley's death is being marked by a quickened interest in his life and writings. The outward signs of this are several; one is a special number (May 1953) of *The British Journal for the Philosophy of Science* wholly devoted to his scientific and philosophical papers. In addition, a set of contributions dealing with some specialist aspects will be found in the *Acta* of the Eleventh International Congress of Philosophy (1953). Manifestly, these represent more than a desire to pay tribute to a great man; they express a conviction that Berkeley has, to some degree at least, been under-valued. In addition, a perusal of his labours shows how great a contribution to our cultural heritage was made during the first half of the eighteenth century by a master mind in an atmosphere free from the ingredients of excessive specialization, and purely departmental thought. Naturally, an intellectual climate of such a kind would not in itself have produced work of such outstanding character as Berkeley's; but it did enable him to flourish to an extent unlikely to be experienced even a century later. Add to this an innate nobility of outlook, a disdain for jargon and all manner of half-truths (including in particular those of the free-thinkers), and the result is a philosopher in the grand manner. Historically, too, this is significant. Berkeley's philosophy was no mere academic exercise; it was a life to be lived and a torch to be carried, not only among the favoured, but more especially into the company of the obscure and oppressed in his diocese of Cloyne. All this needs to be realized before setting out to bring before our eyes of to-day an image of a 'universal specialist'.

In the sequel, too rigid a distinction between Berkeley's original contributions to knowledge and his empirical activities will be avoided. He combined considerable powers of abstraction with a robust common sense all too seldom displayed in a single individual. It may well be doubted whether he would ever have served his generation so effectively had these gifts been present in less perfect balance.

A beginning may conveniently be made with the ***Festschrift*** of *The British Journal for the Philosophy of Science*. The contribution which discusses Berkeley's work and its importance for modern psychology naturally is focused upon his "New Theory of Vision" (1709). Here, stress is laid upon the object of consciousness; without such an object, further ratiocination is meaningless. As the author neatly remarks, there is a world of difference between what is perceived *as* red light, and what the physicist *calls* red light. (Incidentally, how much a recognition of this distinction would have reduced the temperature of the Goethe–Newtonian battle.) Again, Berkeley seems to have accepted what psychologists call a mosaic structure of awareness—a concept very close to what is often called 'and-summations'. This conflicts in essentials with the *Gestalt* outlook, according to which an experience is with things as wholes, in such a way that they cannot just be added up with the 'and' acting as a species of polar bond. Yet it would be a mistake to regard the good Bishop as wholly incorrect here, because the integrated whole is itself a sensory experience, and has nothing to do with *a priori* assumptions, still less with metaphysics.

We now come to Berkeley's views upon the subject of optics as he found it. He tackled the question of the inverted image upon the retina. Two modern developments may be noted: one that of Stratton (1897), and the other the unpublished work of Erismann, who has been able to study the vertical and horizontal relations separately. Yet again, there is the little-known research of von Senden (1932), out of which comes problems of great profundity concerning a subject born blind, who, through operation, is later enabled to see. For Berkeley, engrossed as he was in philanthropic adventures, all this would have but confirmed his belief in learning by experience, even if that experience subsumed only a portion of previous elements.

In the next paper, the emphasis is upon the physiological mechanism involved in the perception of distance. Berkeley is seen as the link between Descartes and Helmholtz. It should be remembered, however, that Berkeley never conducted any appreciable amount of experimentation (his relative isolation probably made it impossible); but his grasp of practical science is remarkable. In a number of ways, his thought has influenced later work.

We now approach what is perhaps the most significant effort which Berkeley ever made in the intellectual sphere. This was his criticism of the infinitesimal. The germ of all this may be found in his two notebooks ("Philosophical Commentaries"), a product of early life. In these, though no professional mathematician, he was running true to type in displaying his best talent while still quite youthful. The attack was delayed until 1734, but then it came in "The Analyst: or a discourse addressed to an Infidel Mathematician". In brief, Berkeley asserted that in putting $x + o$ for x in x^n, and then allowing o to vanish at the final stage, is to go back upon the fundamental assumption of the whole process. The hypothesis was that the increments were something, or at least that there was such a thing as an increment; which done, these increments were themselves taken to be nothing, or that they were even denied existence. Of course, it is not in the nature of things that the matter should rest there; Newton's theory, suitably modified, could in fact be properly secured. But Berkeley's criticism has proved correct, and the infinitesimal-concept has gone. Other examples of the use of the method of fluxions—especially the calculation of the sub-tangent—came in for some rather rough handling: as a matter of history, one effect was to expose the imperfect grasp of the infinitesimal calculus possessed by mathematicians at the end of the century. Even Lagrange and L. N. M. Carnot were content to accept a sort of 'compensation of errors', and to leave it at that.

Reasons are adduced, in the next article, for the conviction that Berkeley anticipated much of Ernst Mach's work. Certainly, as the author remarks, there is a good deal of the new look about it. Moreover, the historical aspect is important: it resides in Berkeley's "protest against essentialist explanations in science". Taken alongside his distinction in the field of Christian apologetics, this is not a little remarkable.

From here, in the next paper, we are invited to consider Berkeley's philosophy of motion. Before doing so, or in fact in the course of doing so, some reflexions come to light upon the state of mind experienced by scholars in dealing with Newton's "Principia". In spite of Berkeley's use of the phrase

"Infidel Mathematician", in another connexion Newton was not "faithless". Yet there is no doubt that the mechanistic concept of the universe exerted a certain fascination upon those who regarded it as a vast conglomeration of machine-like units. It was only natural that Berkeley, the devoted ecclesiastic, should look upon Newton with some concern. The eighteenth century could name Berkeley as a typical product, scarcely so Sir Isaac.

In 1718 Halley discovered the discrepancy—in relation to the catalogue of Hipparchus—in the position of Sirius and of two other stars. To deal with the 'ultimate' background involves successive approximation; but Berkeley almost certainly struck at the root of the problem in his insistence that "no *one* star should be regarded as more favoured than any other".

A following note brings to light the development of a 'descriptive' in contradistinction to an 'essentialist' concept in scientific theory, and shows how, in the fourteenth century, it was directed somewhat critically at Aristotelian physics.

Finally, a detailed treatment of Berkeley's "Querist", with its strong resemblance to the thought of the late Lord Keynes, rounds off a most valuable collection of essays. A brief outline of Berkeley's life forms a fitting conclusion.

In conformity with the opinion already expressed that it is well to see Berkeley's contributions as a whole (not only those which may be taken to add to the sum of human knowledge, and with which the special number of *The British Journal for the Philosophy of Science* was concerned), some account may now be offered of his more *ad hoc* inquiries. These are of necessity practical, and illustrate another facet of this complex character. First and foremost is his preoccupation with tar-water, first mentioned on February 8, 1741. The use of this he advocated unceasingly during the great epidemic in the south of Ireland as a remedy for smallpox. The prescription ran, "A heaped spoonful of rosin, powdered fine in a little broth". A year later, we find this concoction, or something very like it, being recommended as a tonic. Apparently Berkeley was content with the results as he observed them, and made no attempt to devise controlled experiments to support his action. Nevertheless, it was all of a piece with his overwhelming sense of solicitude for suffering, and in keeping with his disdain for "faith without works". With good reason has he been called a theological utilitarian.

His correspondence reveals numerous occasions when the temptation must have been tremendous to take sides in the burning questions which tore the Emerald Isle of his day into countless pitiful fragments; yet we read in the foreword to his "Passive Obedience" (1712) a determination "to preserve that cool and impartial temper which becomes every impartial inquirer after truth". Again, in his "Discourse to Magistrates", he maintains that prejudice is not necessarily false: it was the carelessness of free-thinkers to confuse prejudice with error.

All this needs to be supplemented by an appraisal of his efforts *pro bono publico*, for example, the grand scheme to found a university for the education of American Indians. In fact, for this project he obtained a substantial Parliamentary grant, which never came to fruition.

To-day, we have a likeness of Berkeley in the portrait by John Smibert in the National Portrait Gallery, London, reproduced as a frontispiece in the special number of *The British Journal for the Philosophy of Science*. A fairly recent cleaning has revealed the date 1728 in place of 1725. Mrs. W. S. Lewis, of Farmington, Connecticut, noticed not long since that the promontory in the background closely resembles Paradise Rock, Rhode Island, with a gentle slope down to the sea on the near side of the rock. This resemblance can be clearly seen in a snapshot which she took from near Berkeley's Farm and sent to the National Portrait Gallery. For these details I am indebted to the kindness of Mr. C. Kingsley Adams, director of the National Portrait Gallery.

Berkeley moved to Oxford in 1752, by then an exhausted man. His death occurred early in 1753, when, in the seclusion of Christ Church, he was laid to rest.

F. I. G. Rawlins

THE INTERNATIONAL GEOPHYSICAL YEAR 1957–58

In 1882–83, many nations joined in a great international scientific enterprise, the International Polar Year, in which the geophysics of the polar regions—mainly the Arctic—was intensively studied, and expeditions set up polar meteorological, magnetic and auroral stations and operated them for twelve or thirteen months. In 1932–33 the jubilee of this First Polar Year was celebrated by a repetition and extension of the enterprise, and ionospheric observations were included in the programme.

On April 5, 1950, Dr. L. V. Berkner, at a small gathering of geophysicists at the then home of Prof. J. A. van Allen, Silver Springs, Maryland, U.S.A., proposed a second repetition after twenty-five instead of fifty years, in view of the rapid advances made since 1933 in scientific, especially ionospheric, techniques. Being favourably regarded, this proposal was formally brought before three international scientific bodies in the summer of 1950—the first to meet was the Mixed Commission on the Ionosphere (MCI), formed by the International Council of Scientific Unions (ICSU) under the sponsorship of the International Union for Scientific Radio (URSI) with the co-operation of the International Astronomical Union (IAU) and the International Union for Geodesy and Geophysics (UGGI). The Mixed Commission on the Ionosphere presented the proposal in some detail to the International Council of Scientific Unions, and recommended the formation of a committee to organize a third polar year in 1957–58. The proposals were later endorsed by the International Union for Scientific Radio and the International Astronomical Union in September 1950, and came before the Bureau of the International Council in January 1951; this commended them to its Executive Board, which met in October 1951 and decided to set up a 'special committee' for the purpose, under the direct auspices of the International Council (not a 'mixed commission' of several unions, sponsored by one of them). The choice of members delegated by the Executive Board to the Bureau was made by the latter at its next meeting in May 1952; four members were appointed, representing the International Astronomical Union, the International Unions for Geodesy and Geophysics and for Scientific Radio, and the International Geographical Union, respectively, with Col. E. Herbays, general secretary of the International Union for Scientific Radio, as convener. At the same time, the nations adhering to the International Council were invited to form national committees to organize their participation in the new Polar Year; and through the Moscow Academy of Science, the co-operation of the U.S.S.R. was invited.

In the summer of 1952 the International Union of Scientific Radio set up its own committee to organize the ionospheric and radio parts of the enterprise, and the Mixed Commission on the Ionosphere discussed and made further proposals concerning it. By that time the view had developed among the unions concerned that the enterprise should deal as much with tropical and southern non-polar regions as with the Arctic and Antarctic, and this change was recognized by the Executive Board and General Assembly of the International Council of Scientific Unions meeting in October 1952, which decided to change the name to the International Geophysical Year (Année Géophysique Internationale, AGI), and also: (i) to charge the committee with the organization of a series of new determinations of longitude differences, an operation for which the International Union for Geodesy and Geophysics, supported by the International Union for Scientific Radio, had requested the formation of a new mixed commission of the International Council; (ii) to invite the other interested unions, like the International Union for Scientific Radio, to set up their own organizing committees, the Special Committee of the International Council (CSAGI) continuing with its very limited numbers; and (iii) to welcome the collaboration of the World Meteorological Organization (WMO) in the enterprise and to add a representative of that body to the Special Committee of the International Council.

In October 1952, a preliminary meeting of some of the members of the Special Committee of the International Council was held, and it was decided to renew the appeal (through Col. E. Herbays, who was elected provisional secretary) for the formation of national committees for the International Geophysical Year and the preparation of national plans; to hold its first full meeting in June or July 1953; to define the International Geophysical Year as extending from August 1957 to the end of 1958 (seventeen months); to propose to the International Council of Scientific Unions a moderate increase in its own membership, in view of the wide scope of the enterprise; and to seek financial support for the International Council from the United Nations Educational, Scientific and Cultural Organization, to provide for a secretariat for the International Geophysical Year from the beginning of 1955.

In March 1953 the Bureau of the International Council enlarged its Special Committee to include eleven representatives as follows: International Astronomical Union, N. E. Nørlund and M. Nicolet; International Union of Geodesy and Geophysics, J. Coulomb and P. Tardi; International Geographical Union, J. M. Wordie; International Union for Scientific Radio, L. V. Berkner and M. Boella; International Council of Scientific Unions, S. Chapman and E. Herbays; World Meteorological Organization, J. Van Mieghem and a second member to be appointed. The Special Committee of the International Council thus enlarged held its first meeting at Brussels during June 30–July 3, 1953; in place of MM. Nørlund and Tardi, MM. A. Danjon and G. Laclavère attended, and alternate representatives V. Laursen (secretary of the Association for Terrestrial Magnetism and Electricity of the International Union for Geodesy and Geophysics) and W. J. G. Beynon (secretary of the Mixed Commission of the Ionosphere) attended by invitation, making twelve representatives in all. (Later in July, N. E. Nørlund was succeeded on the committee by H. Spencer Jones, and A. Danjon was appointed formally as an alternative representative.)

On the first day (spent in administrative session), S. Chapman and L. V. Berkner were elected president and vice-president respectively, and M. Nicolet was elected general secretary from November 1; the period of appointment as provisional secretary of the original convener, E. Herbays, has now ended, and his valuable work for the International Geophysical Year and excellent arrangements for the meeting were warmly acknowledged. On the remaining three days, the Special Committee of the International Council met in open session with the participation of 'observers' delegated by several of the national committees for the International Geophysical Year, twenty-five people being present in all, drawn from thirteen countries. E. Herbays reported the formation of further union and national committees, from which twenty-six documents had been received, outlining union or national programmes and proposals. To consider these documents, eleven groups (partly overlapping) were formed from all those present, to deal with (i) meteorology, (ii) latitude and longitude determinations, (iii) geomagnetism, (iv) the ionosphere, (v) auroræ and airglow, (vi) solar activity, (vii) cosmic rays, (viii) glaciology, (ix) oceanography, (x) the choice and announcement of world days for specially intensive observation during the International Geophysical Year, and (xi) publication. These groups, in the work of which the help of the 'observers' was most valuable; each prepared a draft report and associated resolutions, and then, where desirable, held joint meetings to revise and complete their reports. With the aid of the Royal Meteorological Institute of Belgium, these reports and resolutions were typed and duplicated for consideration by the meeting as a whole; with some further modifications, the combined report and resolutions were adopted by the Special Committee of the International Council, to be a general preliminary guide to the unions and national committees. The committee, in conclusion, expressed its warm thanks for the hospitality it had received in many ways, from the Royal Belgian Academies (in whose Palace the meetings were held), from the Royal Meteorological Institute and its director, Prof. E. Lahaye, from Prof. J. Tison, and from Prof. V. Brien.

The scope of the International Geophysical Year is too wide to be indicated here even in outline; the Special Committee of the International Council recommended each national committee to take steps to inform the scientific and general public on the purpose of the International Geophysical Year and the plans for the enterprise. Here only a few major items will be mentioned.

The main meteorological problem to be attacked is that of the general circulation (and the associated thermodynamics), particularly above the troposphere; and special efforts are urged, and in part are assured, for the exploration of the atmosphere up to 30 km. height (at least on certain of the World Days), especially along the three meridians 10° E., 140° E. and 70° W.

These meridians were adopted also for special ionospheric and magnetic investigation. The World Days, on the average five per month, are to be fixed partly in advance (three per month) and partly at short notice according to the existing solar activity and expected degree of magnetic and ionospheric quiet or disturbance; these disturbances are among the major problems to be examined further during the International Geophysical Year. A great improvement in auroral observation is to be aimed at, including aid from air pilots and meteorological officers, and also taking advantage of the new means of detection of daytime auroræ, and of auroræ behind clouds, by radio techniques. The latitude and longitude programme is intended to improve the accuracy of time determination and of star catalogues, and to extend our knowledge of the irregularities in the earth's rotation, of the relative displacements on the earth's surface and displacements of the vertical, and of the time of propagation of radio waves. Limited programmes on glaciology, climatology, oceanography and cosmic rays are also envisaged.

The Executive Board of the International Council of Scientific Unions, meeting in Strasbourg shortly after its special committee met in Brussels, provided funds for the secretariat of the Special Committee up to December 31, 1954, and enrolled it for the time being among its 'permanent services'. The International Union of Pure and Applied Physics (IUPAP), through its representatives, expressed an interest in the International Geophysical Year, particularly in regard to cosmic rays, and it seems not unlikely that it will become a participating union, form a union International Geophysical Year committee, and nominate a representative on the Special Committee of the International Council.

By slow stages the Special Committee of the International Council has been constituted, and with the aid of the national committees for the International Geophysical Year set up at its invitation it has formulated an extensive co-ordinated programme the realization of which in large part may now confidently be expected. But the enterprise will not be fully successful unless all the major nations of scientific culture participate in it; for this reason, at the request of its Special Committee, the International Council of Scientific Unions has formally invited the renewal in this enterprise of the valuable and effective co-operation given by Russia to the first and second International Polar Years; and also has requested that the U.S.S.R. should co-operate in encouraging other nations to take part that have not yet agreed to do so.

SYDNEY CHAPMAN

PRODUCTION OF ANTIBIOTICS AND THEIR USE IN INDUSTRY

A SYMPOSIUM on "Antibiotics—their Production and Use in Industry" was held by the Society for Applied Bacteriology at Oxford on July 7. The discussion was opened by Dr. A. Hirsch (Unilever, Ltd., Bedford), who pointed out the desirability for the continued study of polypeptide antibiotics. At the present time these antibiotics cannot be fully utilized because the necessary chemical knowledge and methods for their development appear to be lacking. In this respect, the peptide antibiotics resemble penicillin and other early antibiotics which were developed long after their first description. Most of the successful methods of protein chemistry concern compounds with a molecular weight of more than ten thousand, while paper-chromatographic methods are useful with compounds of a molecular weight of up to a thousand. The intervening gap is not adequately covered, and even counter-current studies are only of limited value because they rely on the hydrolysis of the very structures which ought to be the object of the study.

The rapidly bactericidal nature of the polypeptide antibiotics renders it unlikely that they act by competing with essential metabolites. Surface activity and consequent absorption of the antibiotics on the bacterial surface have been shown to occur in many cases, and the similarity to the antibacterial action of cationic detergents is very marked. This surface activity may not be the immediate cause of the death of the bacterial cell, but at least it enables the antibiotic to be effective in very minute amounts. Surface activity may also eventually permit of more specific action with smaller toxicity than would be possible with metabolic competitors. It was thought at one time that antibiotics effective against Gram-negative organisms would also be toxic, the structure of Gram-negative cells resembling animal tissues more closely than Gram-positive organisms. The polymyxin antibiotics are, however, selective against Gram-negative organisms, and their toxicity is no greater than that of some other polypeptide antibiotics.

The next speaker was Dr. T. S. Work (National Institute for Medical Research, Mill Hill). He discussed, from the point of view of the comparative biochemist, the reason for the selective action of the medicinally useful antibiotics. Penicillin is about ten thousand times more toxic to some micro-organisms than to animal tissues, and even chloromycetin is some hundreds of times more toxic to bacteria than tissues. The available evidence suggests that penicillin at any rate disrupts the protein metabolism of micro-organisms. This may explain the selective action of penicillin, because proteins are well known from immunological work to be the agents responsible for specificity. The study of the synthesis of protein may therefore give a clue to the selective action of the non-toxic antibiotics.

The synthesis of proteins is currently explained in two different ways. They may be built up, piece by piece, from amino-acids, or they may be formed as on a template, the whole molecule being 'stamped out' in a single operation. The latter explanation is largely favoured by geneticists, who regard the genes as the templates. Should this latter explanation be correct, this process might be difficult to investigate experimentally, and the first explanation offers the best hope to break the process down into small steps capable of study.

The nature of protein synthesis has been investigated in lactating animals injected with radioactive amino-acids. The amino-acids passed rapidly through the mammary barrier and were synthesized in the gland to casein and β-lactoglobulin. Immune globulin, however, was found to pass between the milk and the blood stream and was not synthesized in the mammary gland. After radioactive amino-acids were injected into the blood stream, samples of milk were taken and the casein from it mildly hydrolysed. Twelve separate fractions were collected from a column, and the radioactivity of these was found to be equally distributed. This was strongly suggestive evidence that the synthesis occurred by a template mechanism, since an unequal distribution of radioactivity would be anticipated if the protein was synthesized partly from pre-formed peptides and partly from individual amino-acids.

The industrial fermentation of the commercially prepared antibiotics was discussed by Dr. M. Lumb (Boots Ltd., Nottingham). Many of the antibiotics first described in the United States are now produced in Britain; this has not, however, detracted from the value of penicillin, the production of which is still increasing. The largest manufacturer of penicillin is still the United States with 20 million mega-units/month, followed by the United Kingdom with 4·5 million mega-units/month and Japan with 1·5 million mega-units/month. The expense of penicillin production has decreased in recent years for several reasons. Media now contain the correct precursors (for example, phenyl-acetic acid for penicillin *G*), although it remains true to say that corn-steep liquor is still one of the main ingredients for penicillin production. With the streptomyces antibiotics this substance is not quite so useful, and media still need supplementation with expensive meat extracts. The selection of the best strains of moulds and the addition of fatty acids to the medium are other factors which have increased the yields of penicillin. The parent culture for most of the strains in use to-day is strain 48–701; but this has been adapted to local conditions by different manufacturers. The expensive finishing process of freeze-drying of the early days has also been replaced by cheaper and better methods of crystallization.

The place of the assayist in the production of antibiotics was described by Mr. K. A. Lees (Glaxo, Sefton Park). For routine use with penicillin, dihydrostreptomycin and streptomycin, he advocated agar-diffusion assays with *Bacillus subtilis* as the test-organism and phosphate buffer as the diluent. For most routine assays an error of ±5 per cent is suitable; with increased replication, this can be improved to ±1 per cent, which may be necessary when preparing fresh standards. A particular problem of antibiotic standardization is that of the relative potencies of the streptomycin and dihydrostreptomycin national standards. For example, does 1,000 units of the streptomycin standard when hydrogenated with 100 per cent efficiency yield 1,000 units of dihydrostreptomycin? This problem of the relationship between these two biological standards appears to be unique, and it may warrant the publication of comparative results on the two standards obtained by several independent physico-chemical and biological methods to enable a reasonable estimate of the relationship between the existing standards to be established.

The use of antibiotics for the control of plant diseases was discussed by Dr. P. W. Brian (I.C.I., Welwyn). The antibiotics developed for medicinal purposes, that is, those commercially available, have not proved very satisfactory for plants, and expense, too, has so far been against this application of antibiotics. Further, these antibiotics are more effective against bacterial than fungal diseases, although the latter are economically the more important. However, the fact that antibiotics, unlike other chemical means of control, can be non-toxic to plants and effective in small concentrations has encouraged the continuance of this research along its own lines.

Recent trends have led to the isolation of antibiotics specifically designed against plant pathogens. Antibiotics such as antimycin, hellixin and toximycin are all effective against experimental apple scab disease and against the development of early blight in tomatoes. Griseofulvin is one of the earlier antibiotics recognized for its antifungal properties and is sometimes known as the curling factor. It is relatively not phytotoxic and can be taken up by a number of plants into their tissues; this may give the plants resistance to some diseases. Under some conditions which may prevail in soils, griseofulvin can be stable, and if the producer moulds were present the antibiotic could be formed in the soil. This offers an attractive way of utilizing antibiotics produced *in situ* for the control of plant diseases.

The well-known effect of antibiotics in animal nutrition was described by Dr. J. W. G. Porter (National Institute for Research in Dairying, Shinfield). There is no longer any doubt that penicillin and aureomycin, and to a smaller extent some of the other antibiotics, cause a significant improvement in the growth-rate of some animals. Thus the growth-stimulating effect of antibiotics is estimated at 12 per cent in pigs, 15 per cent in chicks, 30 per cent in turkeys and 20 per cent in calves. The factors affecting the response are mainly the age of the animal, the response being most marked with young and rapidly developing animals, and the composition of the diet, the effect being most noticeable with all-vegetable diets.

The explanation of this phenomenon is still obscure. The bacteriological picture is confused, and, in chickens at least, the workers at Shinfield have not been able to demonstrate a change in bacterial flora as the result of antibiotic feeding. Even so, the evidence remains fairly strongly in favour of the antibiotic combating a sub-clinical form of disease, because the growth-stimulating effect of the antibiotics disappears if chickens are either raised in new premises or are kept under conditions which strictly exclude micro-organisms.

NEW FISH CULTURE METHODS FOR *TILAPIA* IN EAST AFRICA

By J. M. BROWN
Fish Culture Farm, Game Dept., Kenya
AND
Dr VERNON D. van SOMEREN, M.B.E.
River Research Centre, Game Dept., Kenya

VARIOUS species of *Tilapia* are now widely used in African and other tropical countries for fish-farming purposes, their use having been popularized particularly by the intensive work on them in the Belgian Congo.

In many instances, the weight yields from cultivated ponds have been a ton or more per acre per year, figures which are greatly in excess of those obtained in Europe using carp or other temperate region species. In nearly all cases, however, these high weight-yields have been composed largely of thousands of small 'trash' fish—fry and fingerlings which have resulted from unrestricted breeding in the production ponds, with consequent runting of the population.

While it is true that such small fish may be utilized by some African tribes as food, there is no doubt that East African natives, and certainly all Europeans, prefer their fish to be of larger edible size. Early and frequent breeding under tropical pond conditions is indeed the greatest disadvantage of the various *Tilapia* species; and with the various culture methods introduced by Belgian and other workers, it is impossible to ensure that all the fish are of large size when the crop is to be taken at weekly or more frequent intervals, and not by periodic long-term draining of the ponds. The *méthode mixte*, developed by the Belgians, for example, is an effort to overcome this disadvantage, but in itself suffers from other disadvantages in that it is not possible to take a regular crop of fish over a long period of time, and the final draining during which the fish are sorted involves a definite loss of fertility each time the pond is drained; while the smaller fish which are returned to constitute the next stocking are quite uncertain as regards numbers, and already themselves stunted in growth. Other methods which involve the draining of production ponds before breeding has commenced again result in loss of fertility and impossibility of frequent cropping, while the use of predators is still uncertain.

The crux of the matter is always the too frequent breeding of *Tilapia* in ponds, and the necessity for adapting cultural methods to obviate this; as one delegate to the recent Inter-African Symposium on Hydrobiology and Inland Fisheries put it, what is really required in Africa is a method of fish farming whereby "the farmer manages the fish, and not the fish manage the farmer!"

The only practicable method of controlling *Tilapia* breeding would appear to be one by which the sexes can be separated quite surely in the production ponds. With the species commonly used, it is not generally possible to distinguish the sexes in a mixed population of various ages, unless they are fully mature and the males in breeding coloration with other secondary sexual characteristics developed. By this age, the fish have normally bred once or more, and growth has been checked with the onset of maturation. What is required, therefore, is a certain method of sex separation before maturity, and this we believe we have found during the course of experiments at the Fish Culture Farm of the Kenya Game Department at Sagana.

Work here has been concentrated mainly on the indigenous East African species *T. nigra*, which has already been introduced widely into dams in the past, and shows all the usual features of frequent breeding and over-population. This species is, however, one of the genus group in which the males tend to be larger than the females, and we have found that this sexual size-difference is evident several months before maturity, and that it can be used with complete accuracy for separating the sexes before maturity, providing one starts with a batch of fingerlings of known and similar age. It is not possible to separate the sexes by size in a mixed population of various ages. Furthermore, the degree of difference is apparent early and well marked. With high rates of population it is less obvious; a rate of 1,200 fish per acre gives the best result, but even at 2,400 per acre the difference is still practicable.

The technique is simple. Isolated pairs of fish are allowed to produce batches of fry in spawning ponds. When about 5 cm. long (two to three months), batches of fry of similar age are stocked in fingerling ponds at 1,200 per acre. About two to three months later, at an average length of about 10 cm., sexual distinction in length is obvious and of the order of about 2 cm. At this age, a hundred fish are seined, measured to the nearest 0·5 cm., and the length-frequency of the sample calculated. The figures show two clear peaks, those of the larger size being the males; a dividing size-limit is fixed, allowing 0·5 cm. in favour of males (though there is usually little overlap), and all the remainder of fish above this size-limit are separated out. These are all males and are stocked by themselves in the production ponds. Since sex ratios are nearly always even, at least half the fingerlings each time are males. It is, of course, also possible to utilize the females only, but their growth-rate is not as good as in the males.

Such males in production ponds may reach a commercial size of 20 cm. in about eight to nine months from birth; but as before it is advantageous to keep the 'male only' stocking rate at 2,400 per acre or lower. The natural yield of our Sagana ponds, without fertilizing or artificial feeding, is about 250–300 lb. per acre, and this could presumably be increased by the usual cultural methods.

This method, which we term 'monosex' culture, has a good many advantages. It is not necessary to drain the pond to take a crop; thus loss of fertility is avoided. The crop is taken by seining as often as desired, and from time to time the production ponds are recharged with further males in numbers equivalent to the crop taken. Since breeding is completely eliminated, there is no over-population or runting, and the stock-rate can be kept constant. This method is not a sterilization technique, and some of the separated males do in fact mature; but the check in growth is not so marked. We have also found that if mature males the growth of which has already slowed down are also stocked separately at a lower rate in a monosex pond, their growth-rate can be further increased.

This technique has been applied only to *T. nigra*. We have also experimented with *T. melanopleura* introduced from the Belgian Congo; but although the Belgians have shown that sex differentiation in size occurs with this species after about 20 cm., we have found no evidence of this up to 12 cm., at which size they mature in Kenya. Unless the difference is evident before maturity, the technique is not of great value. *T. melanopleura* has not been satisfactory as a farm fish in Kenya, as the death-rate on handling is far higher than with *T. nigra*, and breeding is irregular, with fewer fry per brood.

The second promising technique which we have developed is based on observations of the feeding habits of *T. nigra*. This species is not a plankton feeder but a grazer, utilizing the epiphytic and epilithic algæ in its environment. Although it is known that the Lake Victoria cichlids apparently utilize only the diatoms in their food, *T. nigra* can thrive well on other green algæ such as euglenids, and diatoms only are not essential.

The soft flocculent mud bottom of the normal fish pond is far from ideal for the growth of sessile algæ, since they require a fairly firm substrate upon which to grow—such as the stonework on the inlet and outlet towers or fringing grass, where indeed *T. nigra* may be seen feeding most. We have therefore tried increasing the hard surface available for algæ by suspending screens of papyrus matting vertically in the water (in an east–west direction, so that both sides receive sunlight at this latitude). Results to date show that fish in such 'screened' ponds show a 15–20 per cent increase in growth over similar fish in unscreened ponds. Thus this technique offers a distinct advance in utilizing the full productivity of the pond. The screens develop a good growth of algæ and protozoa in a few weeks, and fish may be seen grazing along them.

Withy hurdles are now proving more lasting and better, and various other possibilities also suggest themselves, such as applying fertilizer purely locally to the screen itself, and not to the pond as a whole, since free plankton is of little use to this species. The main essential is to increase the hard grazing area without diminishing the volume of water appreciably, and trials are now also being made of planting the pond bottom with a mat of controllable vegetation to increase the available area for epiphytic algæ.

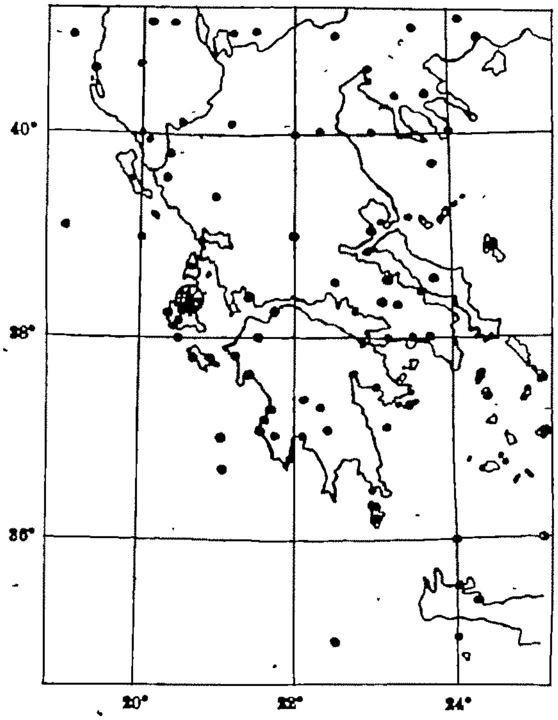
However, simple screening can be carried out easily and cheaply in African fish-ponds, and screens are easily removed to seine the crop. Screening combined with monosex culture (where we shall supply the males) should solve a good many of the local African fish production problems, where shortage of water and natural disinclination for work precludes any of the more complex procedures such as fertilizing, daily feeding or regular cropping to keep up growth.

We are indebted to Mr. Hugh Copley, fish warden, Kenya Colony, for constant encouragement and advice, and for permission to publish this preliminary communication.

EARTHQUAKE SWARM IN THE IONIAN SEA

An earthquake swarm in the Ionian Sea began on August 9, and on August 15 the swarm appeared to be continuing. The epicentres seem to have migrated slightly, but all have been near the Greek islands of Ithaca, Cephalonia and Zante. The earthquakes have not all been of equal magnitude.

The first shock, on Sunday, August 9, at 07h. 41m. 02s. G.M.T., had its epicentre near lat. 38° 19′ N., long. 20° 39′ E. near the islands of Ithaca and Cephalonia. During this earthquake, two hundred houses were destroyed or damaged on the island of Ithaca, three people being killed and fifty injured. The earthquake was registered at Edinburgh with the first pulse *eP* at 07h. 46m. 26s. G.M.T. On Monday, August 10, the shocks continued on the islands of Ithaca and Cephalonia and were strong on the island of Zante. On Tuesday, August 11, an earthquake was registered at the Royal Observatory, Edinburgh, with the first wave *P* at 03h. 37m. 41s. G.M.T. It had its epicentre near the island of Cephalonia at 03h. 32m. 17s. G.M.T. Two villages on Cephalonia, Sami and Aghia Efthimia, were completely destroyed by the earthquake, a hundred and fifty bodies being recovered later from the ruins of the houses and two hundred and fifty people were injured. On the island of Ithaca, the port of Vathy, legendary home of Odysseus, was shaken by the earthquake and also swept by a tsunami or seismic sea wave caused by submarine geological faulting. In Vathy, 98 per cent of the houses were damaged or destroyed. On this day also most casualties occurred on the island of Zante, which had a population of 11,000. The town of Zante was destroyed, three quarters of it being burned by fires occasioned by the scattering of household fires during the earthquake, the water supply having been disrupted. Some three thousand people on Zante Island were rendered homeless.



Greece and Ionian Sea showing previous epicentres (●), and epicentres of August 9 (⊕)

On Wednesday, August 12, the largest earthquake of the present series as yet was registered at Edinburgh (*P* at 09h. 29m. 12s. G.M.T.). The epicentre was near those of the previous three days and the shock originated at about 09h. 23m. 48s. G.M.T. On this occasion the ports of Argostoli and Lixouri on the island of Cephalonia were completely destroyed. At Argostoli, the former British naval base, with a population of 8,300, the prison, along with all other buildings, was reported to have collapsed, the prisoners being marched to the town square under armed escort. The British destroyer *Daring* reported "as we approached we could feel the ship shaking as if distant depth charges were being dropped". Two hundred and fifty casualties were evacuated and seventy casualties remained to be evacuated.

From the coast of Ithaca high columns of smoke arose, and portions of the islands slid into the sea. The Greek Minister, Mr. Adamopoulos, stated that the disaster was greater than that due to the earthquake of April 22, 1928, when part of Corinth was destroyed. The total population of the islands of Cephalonia, Ithaca and Zante was 120,000, and it is estimated that in the present, possibly continuing, swarm there have up to the present time been about a hundred and twenty earthquakes and tremors, some hundreds of people have been killed, thousands injured, 75,000 rendered homeless, and that the material losses have been near £2½ million.

The Alpine folds trend north-north-west to south-south-east through Greece, swing east to west through Crete and continue through southern Turkey in Asia Minor. The zone is one of instability, and gravity anomalies exist. On August 11, 1903, an earthquake occurred in southern Greece with instrumental magnitude 8, and the positions of some recent epicentres are shown on the accompanying map. Earthquakes have occurred previously with approximately the same epicentral position as the present swarm. During the year 1896, the island of Zante was shaken by 306 earthquakes and tremors. From a focus with epicentre at lat. 38° N., long. 20½° E., earthquakes occurred on January 24, 1912 ($M = 6\frac{3}{4}$), March 9, 1932, and September 20, 1939 ($M = 6\frac{1}{2}$). From a focus with epicentre at lat. 38° N., long. 20° E., an earthquake occurred on February 14, 1943, and from a focus with epicentre at lat. $38\frac{1}{2}$° N., long. $20\frac{1}{2}$° E. an earthquake occurred on January 7, 1943 ($M = 5\frac{1}{2}$); the last-named had a depth of focus of 100 km., the others being from somewhat more shallow foci.

ERNEST TILLOTSON

OBITUARY

Prof. R. von Mises

PROF. VON MISES, who died on July 14, had a world-wide reputation among applied mathematicians and aerodynamicists. He was born in Austria on April 19, 1883, and was educated in Vienna, where he obtained his doctorate in 1907. After holding the posts of lecturer, extraordinary professor and professor at Bruenn, Strassburg and Dresden respectively, he was appointed professor of applied mathematics and director of the Institute for Applied Mathematics at the University of Berlin in 1920. He held this post until 1933, when he left Germany to occupy a similar position at Istanbul during 1933–39. He then migrated to Harvard University, where he was first a lecturer and associate professor during 1939–43 and afterwards Gordon MacKay professor of aerodynamics and applied mathematics during 1943–53.

His scientific work covered the whole of mechanics, including elasticity, as well as the theory of probability and statistics, and the philosophy of science. But he will be remembered especially for his researches in theoretical and applied fluid mechanics. To this subject he made numerous contributions, including the theory of aerofoil design and the theory of boundary layer flow.

He had a great influence on the development of mechanics. He inaugurated the famous *ZAMM* (*Zeitschrift für Angewandte Mathematik und Mechanik*) and edited it from 1920 until 1933. In the United States he was editor of "Advances in Applied Mechanics" during 1948–53. His publications number some 142 papers and books on technical hydromechanics, the theory of flight, differential and integral equations of mechanics and physics, the theory of probability, and some writings on positivism.

He had also a great love for literature and possessed a famous collection of books dealing with the writings of Rainer Maria Rilke, to whose work he himself devoted seven articles.

A memorial volume to celebrate his seventieth birthday is in preparation. He leaves a widow, Dr. Hilda von Mises, herself a well-known mathematician. His gracious and lovable personality will be greatly missed.

G. TEMPLE

NEWS and VIEWS

Department of Scientific and Industrial Research, New Zealand

MR. L. W. TILLER AND MR. I. D. DICK have been appointed assistant secretaries to the Department of Scientific and Industrial Research, New Zealand. Mr. Tiller will be responsible for the agriculture and biology group of branches of the Department, and Mr. Dick for those of physics and geology.

Mr. L. W. Tiller

MR. L. W. TILLER was born in Nelson and attended Nelson College. He graduated B.Sc. from Victoria University College in 1921, and in 1922 joined the staff of the Cawthron Institute, where he was engaged in agricultural chemistry and fruit nutritional and cold-storage investigations. From there he went to the Appleby Research Orchard of the Department of Scientific and Industrial Research, in charge of more extensive fruit-tree manurial and storage work. In 1936, he was sent to England in charge of the recording of a large experimental consignment of fruit. While in England he studied at East Malling and Long Ashton Research Stations, and at the Cambridge Low Temperature Research Station. On return to New Zealand, Mr. Tiller was appointed fruit research officer of the Department. During the War he and another officer of the Department initiated experiments on vegetable dehydration and later he co-ordinated the work on full-scale commercial production. He also collaborated with the Army and Royal Air Force in producing special combat rations for all three branches of the Armed Services. In 1947 he was appointed director of food and fruit research, one of his activities being collaboration with British research workers in making temperature surveys on new refrigerated ships. Since 1948 he has been deputy assistant secretary (agriculture and biology). In this capacity he has been closely associated with the sections of the Department investigating fruit, tobacco, hop and entomology problems and plant diseases.

Mr. I. D. Dick

MR. I. D. DICK was born at Napier, and graduated in mathematics in 1939. He was appointed a mathematician to the Department to work on problems in mathematical statistics, which were becoming increasingly important in agricultural research. In 1941 he was transferred to the Radio Development Laboratory (established during the War as a separate unit of the Department) to work on the design and development of aerial systems for radar equipment. He left the Laboratory early in 1944 to undertake operational research in Australia as a serving officer in the New Zealand army. In 1945 he went to the Middle East and Italy, serving as a gunner in the artillery. Mr. Dick rejoined the Department in 1946, and was appointed officer in charge of the Biometrics Section. With the extension of mathematical work, this Section became the Applied Mathematics Laboratory in 1949, with Mr. Dick as director.

Technological Education in Great Britain

REPLYING for the Government in an adjournment debate in the House of Commons on July 23, regarding the provision of courses in technology at technical colleges for students living outside the boundary of the local authority maintaining the college, the Parliamentary Secretary to the Ministry of Education, Mr. Kenneth Pickthorn, said that the principle of regionalism is fully accepted by the Government although it is realized that it may not always be possible to provide in any one college all the courses which students might desire. He thought that there should be little difficulty in making satisfactory arrangements for those students living outside the boundary of the local authority responsible for the college, and he confirmed the Ministry's recognition of the importance of technical and technological development and the vital part which research plays in such development. Nevertheless, it was apparent from Mr. Pickthorn's reply and Mr. William Wells's opening speech that there is little prospect of getting an effective central policy for technical education while it remains under the control of local education authorities, and indeed of the Ministry of Education. The need was again clearly demonstrated for placing the responsibility for higher technological education fairly and squarely on one body closely concerned with university education, such as the University Grants Committee.

Joint Commission on Electron Microscopy

By agreement with the International Council of Scientific Unions, a Joint Commission on Electron Microscopy has been formed, which is made up of four participating International Unions, represented as follows: International Union of Pure and Applied Chemistry, Dr. A. S. McFarlane (Great Britain) and Prof. R. Signer (Switzerland); International Union of Biological Sciences, Prof. L. Bugnard (France), Prof. Irene Manton (Great Britain) and Dr. F. O. Schmitt (United States); International Union of Crystallography, Dr. R. W. G. Wyckoff (United States); International Union of Pure and Applied Physics (the parent Union of the new Commission), Dr. G. Dupouy (France), J. B. le Poole (Netherlands) and Mr. F. W. Cuckow (Great Britain). The Joint Commission is now organizing an international conference on electron microscopy which will be held at the London School of Hygiene and Tropical Medicine during July 6–9, 1954; further details of the conference will be announced later. All communications regarding the Joint Commission should be addressed to Mr. F. W. Cuckow, Provisional Secretary, Joint Commission on Electron Microscopy, Institute of Cancer Research, Royal Cancer Hospital, London, S.W.3.

East African Industrial Research Board: Report for 1952

The tenth annual report of the East African Industrial Research Board covers the year ended December 31, 1952 (pp. 20. Nairobi: East African High Commission, 1953). Full agreement between the East African Governments on the future of research has not yet been reached, and until a permanent organization is established, activities cannot be extended to include civil engineering or metallurgical investigations on the scale desirable. Investigations on hecogenin were concentrated on the pilot-scale production of material containing crude hecogenin from waste obtained in the dry decortication of sisal, and the National Research Development Corporation and the Medical Research Council were supplied with material for use in the synthesis of cortisone. The possibility of separating the niobium mineral pyrochlore from an apatite concentrate obtained from Sukulu soil is being investigated. Triple superphosphate has already been obtained satisfactorily from Sukulu apatite. Investigations of the most economical method of binding fine kyanite for heating in a rotary kiln indicate that pelletizing the powder with molasses gives the best results. A clay deposit has been found near Nairobi from which a satisfactory drain-pipe body can be prepared that will take a lava glaze. Cement clinker giving satisfactory strength tests has been prepared from a mixture of four clays when the interior of a stationary oil-fired kiln was modified so that it was more like a muffle furnace. The study of the fermentation of vegetable matter, such as sisal and papyrus, has been commenced, with the objective of utilizing methane from such fermentation for drying, for the generation of power or as a motor fuel. A full account of preliminary experiments leading to work with a semi-pilot scale digestor on the gaseous fermentation of sisal waste is appended to the report. The gas obtained consists chiefly of carbon dioxide and methane in the ratio 2 : 3 by volume. Other appendixes deal with the purification of diatomite obtained from deposits in Kenya and with methods of improving the setting qualities of plaster of paris obtained by calcining local gypsum.

Max Planck Association for the Advancement of Science

In 1945 the German Research Institute, Berlin-Dahlem, was set up, incorporating the organization formerly known as the Kaiser Wilhelm Institute and Research Establishment. The German Research Institute has now been dissolved, with effect from July 1, and has been joined to the Max Planck Association for the Advancement of Science (headquarters: 10 Bunsenstrasse, Göttingen). The following institutions in Berlin-Dahlem (with number and name of street as shown, followed by the name of the director in brackets) have therefore been taken over by the Max Planck Association: Max Planck Institute for Comparative Genetics and Congenital Pathology, 26–28 Ehrenbergstrasse (Prof. Hans Nachtsheim), and the Department of Tissue Research, 9 Garystrasse (Prof. (Mrs.) Else Knake); Fritz Haber Institute of the Max Planck Association, 4–6 Faradayweg (Prof. Max von Laue); Berlin Department of the Max Planck Institute for Foreign Public Law and International Law, 1 Boltzmannstrasse (Dr. Erich Kraske); Max Planck Institute for Cell Physiology, 32 Garystrasse (Prof. Otto Warburg); Research Establishment for the Recording of Plant Cultures in the Max Planck Association, 16 Faradayweg (Prof. (Mrs.) Elisabeth Schiemann); Research Establishment for Micromorphology in the Max Planck Association, 16 Faradayweg (Dr. J. G. Helmcke).

Stranded Whales and Turtles

The systematic reporting of stranded whales, dolphins and porpoises to the British Museum (Natural History) came into operation in 1913. The keeper of zoology at that time, Sir Sidney F. Harmer, was responsible for starting the scheme, and with the willing co-operation of the Board of Trade and other competent authorities, a valuable supply of material and data has since been sent to the Museum. Up to the present, 1,041 specific identifications of stranded cetaceans have been made. As a result, certain species thought to be rare are found to be commoner than previously believed, and two new species have been added to the British list. Receivers of wreck and the officers of the Coastguard Service have been mainly responsible for sending in reports and the carcases or the portions of them forwarded to the Museum. The Royal Scottish Museum, the Department of Lands and Fisheries and the National Museum of Ireland, Dublin, and many private individuals interested in marine mammals have also rendered valuable help. As a further aid to all those who are interested, the British Museum (Natural History) has re-issued a pamphlet on the subject (British Museum (Natural History). Guide for the Identification and Reporting of Stranded Whales, Dolphins, Porpoises and Turtles on the British Coasts. By F. C. Fraser and H. W. Parker. Second edition. Pp. viii+42. (London: British Museum (Natural History), 1953.) 2*s*.). The purpose of the pamphlet is to combine in one publication the advice relating to stranded whales, dolphins and turtles issued by the Museum in the past. It is also hoped that the figures and descriptions may help those concerned to distinguish the various species with greater certainty and so add to the interest already demonstrated in this work.

Rats and Mice

In an attempt to reduce the appalling waste of food each year in Great Britain, the Ministry of Agriculture and Fisheries has revised its original bulletin on rats and mice on the farm (Ministry of Agriculture and Fisheries. Bulletin No. 30: Rats and Mice on the Farm. Eighth edition. Pp. iv+17+8 plates. (London: H.M. Stationery Office, 1953.) 2*s*. net). The bulletin is an attempt to explain in simple language the fundamental principles of rodent control, and to provide the farmer with sufficient information to enable him to take effective preventive and control measures. As a means of identification, details are given of the common rat, ship rat and house mouse, while some useful hints are provided on the means of proofing new and old buildings against attacks by these rodents. Means of using poison baits, gases and traps are described, as are the farmer's statutory responsibilities under the Prevention of Damage by Pests Act of 1949.

Milk Pasteurization

A PROFUSELY illustrated monograph on milk pasteurization has just been published in the World Health Organization monograph series (World Health Organization. Monograph Series No. 14: Milk Pasteurization, Planning, Plant Operation and Control. By Dr. H. D. Kay, J. R. Cuttell, H. S. Hall, Dr. A. T. R. Mattick and A. Rowlands. Pp. 204. (Geneva: World Health Organization; London: H.M. Stationery Office, 1953.) 10 Swiss francs; 12*s*. 6*d*.; 2.50 dollars). The monograph, which has been published jointly by the Food and Agriculture and the World Health Organizations of the United Nations, has been written by British authorities and contains a digest of the most up-to-date information on the various stages of milk pasteurization, from the planning of a suitable pasteurization plant to the drawing-up of legislation concerning the handling and treatment of milk. The first essential in milk pasteurization is a satisfactorily designed and well-equipped dairy building. The problems involved in determination of the site, choice of processing methods, planning the layout of the building, and selection of construction materials are fully discussed in the monograph, while the three most generally accepted methods of milk pasteurization and the type of plant required for each are described. The operation of the plant is considered in detail, and standards for pre-pasteurization and pasteurization procedures are clearly defined.

Phosphate Absorption and Utilization by Barley

SINCE the processes of absorption and translocation are closely interrelated in the intact plant, the nutrient content of roots is both determined by the balance of these processes, and is a factor determining their rates. The value of using radioactive tracers in exploring these phenomena is emphasized and exemplified by R. Scott Russell and R. P. Martin in a study of the absorption and utilization of phosphate by young barley plants (*J. Exp. Bot.*, **4**, 10, 108; 1953). Two problems were selected for an initial investigation, namely, the relationship between the external concentration and the rate of absorption of phosphate in actively growing plants; and the relationship between the amount absorbed and the pattern of distribution. The experiments were carried out in water culture with radioactive phosphate supplied over a range of 0·0003–30·0 p.p.m. phosphorus. When the external concentration of phosphate is reduced below 10 p.p.m. phosphorus, the proportion of the absorbed phosphate found in the shoots is markedly reduced. Plants treated with low concentrations of phosphates lose recently absorbed phosphate to the outer medium when transferred to phosphate-free solutions: plants treated with higher concentrations lose a smaller proportion of recently absorbed phosphate. Different balances of other nutrients do not appear to affect the general relationship between the absorption and distribution of phosphate, though quantitative changes occur. The authors conclude that phosphate retention in the roots induced by dilute media is a direct consequence of the small quantity of phosphate entering the roots and is not attributable to the effects of other ions which may be simultaneously absorbed.

Maintenance of Physical Standards

A TWO-DAY symposium on "Recent Developments and Techniques in the Maintenance of Standards" was held at the National Physical Laboratory, Teddington, during May 21–22, 1951 (see *Nature*, **168**, 594; 1951), and the full proceedings, containing the individual papers presented and the discussions which followed them, have now been published (pp. 100+15 plates. London: H.M.S.O., 1952; 4*s*. 6*d*. net). The contents are divided into six sections dealing with primary load standards, the standard of length, standards of radioactive isotopes, temperature, the standard of light and standards of frequency. Each section consists of two papers, one by a delegate from overseas and the other by a member of the staff of the Laboratory. Research physicists will be interested in the new methods and apparatus proposed or constructed for attaining and improving the extremely high order of accuracy and precision of measurement of the fundamental physical standards; and, in addition, teachers of physics will welcome this up-to-date account of, for example, the light-wave standard of length, or measurements of the velocity of light.

National Museum of Wales: Report for 1951–52

THE forty-fifth annual report of the National Museum of Wales, covering the year 1951–52, is as usual an interesting and far from stereotyped document (pp. 34+4 pl.; Cardiff: the Museum, 1952). It reveals the many facets of the intense vitality of this Museum, not the least being the large amount of advice on technical matters given by the staff. In geology, advice to various Ministries and other organizations was given on thirty-nine occasions, involving a total of eighty-one hours of work. In botany, 1,078 determinations were made for members of the general public, and 115 inquiries dealt with. The Zoological Department dealt with 370 inquiries, of which 158 were concerned with the identification of specimens and 212 with the preservation of material, economic problems, and advice on students' theses. In the Department of Archæology a total of 457 individual inquiries were dealt with, either verbally or by correspondence. This included 262 inquiries on numismatics, involving 448 identifications. In addition, thirteen special reports were prepared in response to requests for technical information. A total of 493 inquiries were dealt with at the Welsh Folk Museum. This is an impressive record and an indication of the valuable part played by the National Museum in the communal life of the Welsh.

Leeds City Museums

The Committee of the Leeds City Museum has issued a handy guide-book to the collections and their display at the moderate price of 6*d*. A historical introduction concerning the Museum is followed by notes on animal characteristics and by a description of the four bays in the main gallery devoted to the natural history of Yorkshire. The guide-book concludes with references to the cases illustrating the story of man and some special exhibits mainly of local interest. It is well illustrated with photographs and pencil sketches of Yorkshire scenery.

Exhibition of X-ray Crystallographic Equipment

The X-ray Analysis Group of the Institute of Physics will hold its autumn conference in London during November 20–21, and an exhibition of X-ray diffraction equipment will be an important feature of it. Offers of exhibits are invited under two headings: (*a*) apparatus commercially available in Great Britain, and (*b*) examples of recent developments in X-ray crystallographic equipment that have been made in universities and other research centres in Britain. Examples of the kind of exhibit envisaged are: X-ray tubes, diffraction cameras of all types, microbeam techniques, counters and counter-spectrometers for diffraction work, aids to interpretation, monochromators, microdensitometers, travelling microscopes, X-ray films and photographic accessories, and spectrometers for fluorescent analysis. Owing to the limited space available, a selection will have to be made from the offers submitted. Offers of exhibits giving details of approximate bench and floor space required and of any services needed should be submitted before September 1 to the Conference Secretary, Mr. H. J. Goldschmidt, c/o Institute of Physics, 47 Belgrave Square, London, S.W.1.

Institute of Metal Finishing: Officers for 1953–54

The following have been elected officers of the Institute of Metal Finishing for 1953–54: *President*, Dr. J. W. Cuthbertson; *Vice-Presidents*, Dr. S. G. Clarke, Dr. G. E. Gardam, R. A. F. Hammond, Dr. T. P. Hoar, F. Mason, R. W. Nicol, E. A. Ollard and C. Wharrad; *Honorary Secretary*, Dr. S. Wernick; and *Honorary Treasurer*, F. L. James.

Announcements

Emeritus Prof. W. L. Waterhouse has been elected an honorary life member of the Australian Institute of Agricultural Science in recognition of his outstanding contributions to agricultural science in Australia. Prof. Waterhouse recently retired from the position of research professor in the Faculty of Agriculture, University of Sydney.

The Research Fund of the Chemical Society provides grants for the assistance of research in all branches of chemistry. About £700 a year is available for this purpose, the income being derived from a donation of the Worshipful Company of Goldsmiths, from the Perkin Memorial Fund, and from other sources. Applications for grants should be submitted to the General Secretary, Chemical Society, Burlington House, Piccadilly, London, W.1, on the appropriate form not later than November 14.

The Universities Federation for Animal Welfare is holding a summer school during September 19–26 at Westham House, Barford, Warwick. The school will consist of a number of lectures on various aspects of animal welfare, together with films, excursions, etc.; at the same time the Veterinary Section of the Federation will be holding its annual general meeting. The fee for the course is 5 guineas (3 guineas for students). Further details can be obtained from any branch secretary of the Federation or from Miss M. P. Williams, Branch Organizer, UFAW, 7 Red Lion Square, London, W.C.1.

The Atomic Energy Research Establishment, Harwell, is organizing the seventh of its specialized courses on the design, use and maintenance of electronic instruments used in nuclear physics, radiochemistry and work with radioisotopes, all the subjects dealt with being entirely unclassified. The course will be held during September 28–October 2 at the Isotope School (which is outside the security fence), and applications are invited from physicists and electronic engineers holding a degree or equivalent qualification. The course is limited to twelve persons and costs 12 guineas; board and lodging can be provided at a charge of 7 guineas. Application forms (to be completed by September 11) and further information can be obtained from the Electronics Division, A.E.R.E., Harwell, near Didcot, Berks.

The Institute of Personnel Management, in collaboration with the Personnel Management Branch of the Ministry of Labour, is organizing a five-day residential study-course on "Employment and Welfare", to be held at the Coburg Court Hotel, Bayswater Road, London, W.2, during September 6–11. The course, which is limited to twenty persons, is designed for personnel officers and others who are responsible for such matters as recruitment, selection, personnel records and welfare services. The fees are 10 guineas for the course (9 guineas to members of the Institute) and £8 15*s*. for board and lodging. Registration forms, to be completed as soon as possible, and further information can be obtained from the Courses Secretary, Institute of Personnel Management, Management House, 8 Hill Street, London, W.1.

TECHNICAL PROBLEMS OF THE EXPANSION OF TELEVISION IN BRITAIN

IN October 1952 the Postmaster General set up a Television Advisory Committee, charged primarily with the task of advising on the development of television and sound broadcasting in Great Britain at frequencies greater than 30 Mc./s., and the Committee has now published its first report*. This is an important document, for it lays bare the basic technical difficulties of completing the present single-programme network in Great Britain to cover almost completely the whole of the country and of building up another network (or networks) with allowance in the frequency spectrum for the possible extension of the programmes to colour. These difficulties are not insuperable, but they do present problems the existence of which the non-technical public is possibly unaware, and probably the biggest factor operating against their solution is not the technical one but that of finance. In the present controversy that is brewing in Great Britain on the establishment of commercial radio and television in competition with the present monopoly of the B.B.C., these technical difficulties and their inherent financial consideration should not be overlooked.

Besides television there is the problem of higher-frequency sound broadcasting, such as frequency-modulation transmissions, a development which has not made much progress in Britain (probably owing to the excellence of the present amplitude-modulation system and the efficacy of using medium-waves to cover a relatively small island situated in temperate latitudes); nevertheless, if the present service is to be improved and further programmes developed, the experience of other countries indicates that this is a matter which will have to be taken up, and the Committee specifically states that it will be the subject of a future report.

The nature of television requires high carrier-frequencies, and under international agreement the frequency bands allotted for television (and higher-frequency sound broadcasting) are five in number, as follows: (1) 41–68 Mc./s.; (2) 87·5–100 Mc./s.; (3) 174–216 Mc./s.; (4) 470–585 Mc./s.; and (5) 610–960 Mc./s. Bands 1–3 are generally known as 'very high frequencies' (V.H.F.), and Bands 4–5 as 'ultra high frequencies' (U.H.F.). A Technical Sub-Committee under the chairmanship of Dr. W. G. Radley, engineer-in-chief of the General Post Office, and composed of nine other members drawn from the Post Office, the B.B.C., the radio industry, the Department of Scientific and Industrial Research and the University of London, was set up to consider these bands, and their conclusions form the basis of the present report.

Assuming the continuation of the B.B.C.'s 405-line system, a monochrome television programme requires a channel-width of 5 Mc./s. On this basis, Band 1 is scheduled to be completely used up in supplying the present B.B.C. service to 90–95 per cent of the population of Great Britain (at the time of the report about 78 per cent was covered). Band 2 is too narrow to be of much use for television, and it is proposed that it should be left for the provision of additional sound services.

Band 3 will accommodate eight channels and is very suitable for television. Unfortunately an arrangement has already been made in Great Britain whereby the part of the band between 174 and 210 Mc./s. could be used for private communication and broadcasting services, so that a number of business firms and other organizations are, in fact, using equipment within these frequencies; and further to this, on an international level, a number of radio navigational services have been set up in the other part of the band, between 200 and 216 Mc./s. At the moment the only part of Band 3 that could be immediately used for television are two channels situated in the range 184–195 Mc./s. On the basis of these two channels being used for a second television programme, it would only be possible to set up three or four high-power stations situated in densely inhabited areas, and this would cover not much more than half the total population. The Committee therefore strongly recommends that a third channel be made available in Band 3 (or adjacent to Band 3) so that 70 per cent of the population can be served, and it also emphasizes the eventual necessity of clearing the whole band, though this will cause considerable expense because of the existing equipment already operating on these frequencies.

In Bands 4 and 5 it is recommended that any possible allocation should be done on the basis of every third 5-Mc./s. channel, so as to provide room adjacent to each channel for broadcasting the additional signal information that will be necessary for a programme in colour; in this connexion, the Committee is of the opinion that any extension of a television programme to colour should only be done in such a manner that existing sets can continue to receive the programme in monochrome. The preliminary recommendation for Bands 4 and 5 are that allocations should not go beyond 700 Mc./s., and thus, in all, provision can be made for about fifty stations. The trouble with Bands 4 and 5 compared with Band 3 is that they require a minimum field-strength for reasonable reception of about 3 mV./m. as against 0·3–0·5 mV./m. for the latter, and therefore to cover a given area at the higher frequencies requires relatively many more transmitters. In addition, the receiving equipment will cost more, particularly adaptors for converting the signal to lower frequencies that can be handled by sets working at the existing frequencies; in fact, it can generally be said that a great deal of work remains to be done in the development of cheap mass-produced valves, circuits and aerials for the higher frequencies on the same scale as has already been done for components operating at existing lower frequencies.

The last part of the Committee's report deals with general considerations, some of them rather tentative, of the various claims for frequencies that may be, or have been, made by various interests, and the different ways that these claims can best be met. To complete the report, there are four folding maps of Great Britain, the headings of which indicate the information that they give: the possible use of two channels from Band 3 for television stations; estimated coverage planned by the B.B.C. for their first television programme; estimated coverage planned by the B.B.C. for a second television programme assuming the use of six channels in Band 3; and competitive television—approximate transmitter sites and powers as requested by various applicants for licences.

---

* General Post Office. First Report of the Television Advisory Committee, 1952. Pp. 14+4 maps. (London: H.M.S.O., 1953.) 1*s*. 6*d*. net.

Some of the detailed matter raised in the last part of the report will obviously cause controversy. For example, there is the question of whether the B.B.C. should be granted its request to set up low-power stations on the two free frequencies in Band 3 so as to complete its present national programme or whether it should be forced to use either Band 1 (if this is technically possible) or Bands 4 and 5. Then, as already mentioned, who is to have these two channels for the high-power transmission of a second programme to cover the densely populated regions of Britain, and should this be immediately supplemented by a third channel? From this, one is led to the problem of freeing completely the whole of Band 3; but if television is going to make considerable headway in Britain, even this is not enough, and serious attention will obviously have to be paid to Bands 4 and 5.

Some persons may feel that the actual developments which have taken place so far are such that all this speculation is rather nebulous and that to introduce at this juncture some licensing authority armed with strong powers would be premature because the economic state of Britain in the present conditions of world tension will effectively prevent rapid expansion for many years to come. However, this point of view is refuted by one member of the Committee who, in a minority report, points out that we are already near the point of actually using Band-3 frequencies for a television programme; but because various organizations have been allowed channels on this band for their own private purposes, it is effectively used up, and much money will have to be expended to move them to other frequencies—a financial liability which apparently neither the State nor the organizations concerned are showing much inclination to shoulder.

All this points to the fact that perhaps it would be best in the long run for all concerned if some sort of policy could be formulated now and put in the hands of an effective authority so that the frequency spectrum, which, it seems, is all too small, can be economically shared out in a manner that generally meets with public approval.

AMERICAN PHYSICAL SOCIETY AND THE AMERICAN ASSOCIATION OF PHYSICS TEACHERS

ANNUAL MEETING

THE 1953 annual meeting of the American Physical Society and the twenty-second annual meeting of the American Association of Physics Teachers were held simultaneously at Harvard University, Cambridge, Mass., during January 22–24. In spite of the change of venue from New York City where the past annual meetings had been held, the meetings were well attended with a registration of 1,833 and with more than three hundred ten-minute papers, in addition to longer invited ones, contributed to the various sessions of the two bodies.

At the joint ceremonial session during the afternoon of January 23, the retiring presidential address of the Society was delivered by Prof. J. H. Van Vleck (Harvard University), who took as his subject "Two Barrier Phenomena". In this address he first discussed the barrier which current immigration policies of the United States raises to the entry of visiting foreign scientists, and then described the various theoretical developments which have been required in order to keep pace with the experimental advances in the microwave spectroscopy of ammonia. The Oersted Medal of the Association was presented to Prof. R. M. Sutton (Haverford College), who responded by discussing the heritage of a physics teacher[1], and the eleventh Richtmyer Memorial Lecture was delivered by Prof. E. M. Purcell (Massachusetts Institute of Technology), who took as his subject "Nuclear Magnetism". The after-dinner speaker at the banquet in the evening was Prof. J. A. Stratton (Massachusetts Institute of Technology), who gave an outstanding address on thoughts on technical education stimulated by a visit to Britain, in which he compared education in Great Britain and the United States.

The banquet was also the occasion of the presentation of the first O. E. Buckley Solid-State Physics Prize to Dr. W. Shockley, research physicist at the Bell Telephone Laboratories, for his contributions to semiconductor research. The prize (1,000 dollars), which is administered by a committee of the Physical Society, was established in 1952 under an endowment of a 50,000-dollar trust fund provided by Bell Telephone Laboratories in honour of the Laboratories' former president, O. E. Buckley, who retired recently after thirty-eight years in administrative and scientific posts with the Bell System.

At the business meeting of the Society the following were elected to hold office for 1953: *President*, E. Fermi; *Vice-President*, H. A. Bethe; *Secretary*, K. K. Darrow; and *Treasurer*, G. B. Pegram. A welcome abatement in the rate of expansion of the *Physical Review* was reported by the managing editor, and the treasurer indicated that the present satisfactory position did not call for any further change in the dues and charges.

The twenty-eight invited papers contributed at the scientific sessions of the Physical Society included: a group of three papers by members of the Brookhaven National Laboratory describing new and prospective accelerators at the Laboratory; a separate session in which P. W. Bridgman, G. R. Harrison, G. F. Hull and E. C. Pollard delivered papers dealing with, respectively, recent results at high pressures, échelle spectroscopy, experimental discoveries announced in the programme of the meeting of fifty years ago, and physical studies of viruses; at the symposium of the Division of Electron Physics, individual contributions by M. O'Day (Air Force Cambridge Research Centre) on electron physics in the upper atmosphere, and M. S. Livingston (Massachusetts Institute of Technology and the Brookhaven Laboratory) on the strong-focusing synchrotron; and at the symposium of the Division of Fluid Dynamics, papers on turbulent flow and on phenomena at supersonic speeds. Solid-state physics was represented by contributions by J. A. Hornbeck (Bell Telephone Laboratories) on semiconductors, and P. D. Johnson (General Electric Co.) on luminescence in solids; and in addition to that by F. Bitter on magneto-resonance and magnetic optics, there were several papers dealing with paramagnetic resonance and nuclear resonance. G. Lindström (Nobel Institute of Physics) discussed the establishment of an absolute energy scale in beta-ray spectroscopy, and H. V. Neher (California Institute of Technology) spoke about cosmic rays at high altitudes and latitudes. The only contribution on theoretical physics was by J. Schwinger, who dealt with some formal developments in quantum mechanics. The complete list of invited and other papers, together with abstracts, is given in the minutes of the meeting[2].

The programme[3] of the meeting of the American Association of Physics Teachers consisted of thirty-six contributed papers, two invited papers and two round-table discussions on "Physics beyond General Physics for Non-Physics Majors" and "Undergraduate Laboratory Teaching". The former discussion was mainly concerned with physics requirements for engineering students; there was general agreement that instruction in physics should not be transferred from departments of physics to those of engineering, and the question of the use of the 'slug' and the general topic of units was deferred to the next annual meeting. At the business meeting of the Association on January 24, it was agreed to confer honorary membership on R. Pohl, professor of physics in the University of Göttingen, and on J. H. Keenan, professor of mechanical engineering in the Massachusetts Institute of Technology, and to award citations to H. K. Hughes, for his painstaking work as chairman of the Committee of Letter Symbols; E. C. Kemble, as chairman of the Coulomb Law Committee; T. H. Osgood, as editor of the *American Journal of Physics*; R. R. Palmer, as programme chairman of the Association's meetings in 1952 and 1953; K. Lark-Horovitz, for his teaching activities; and to M. W. White, for his successful efforts on behalf of the Association. The following were elected to hold office for 1953: *President*, P. E. Klopsteg; *President-elect*, M. White; *Treasurer*, F. W. Sears; and *Secretary*, R. F. Paton.

OROGRAPHIC CIRRUS CLOUDS

IT has long been recognized that the forced ascent of air over mountains can produce cloud. Only in the past twenty years has it been realized that thin clouds 10,000 ft. or more above the mountains and with no cloud beneath them may owe their existence to the presence of the mountains. Such clouds are not formed by the direct lifting of the lower air up to cloud-level but in the ascending currents of a system of waves which can be produced by the mountain in somewhat the same way that a rock on a river bed produces waves downstream. The wind and temperature structures of the air have to fulfil certain conditions, as Dr. R. S. Scorer, of the Department of Meteorology, Imperial College of Science and Technology, London, has shown. The favourable conditions are an increase with height of both wind-speed and of the temperature lapse-rate. An inversion of temperature in the lower layers of the air followed by a rapid fall of temperature higher up is a favourable arrangement; but a steep fall of temperature with height low down, such as occurs on sunny afternoons, is unfavourable. When the temperature structure is right for waves to form, there must be sufficient water vapour at some height if a cloud is to appear in the ascending currents of the waves at that height.

The Moazagotl clouds which form at 12,000 ft. or more above the Riesengebirge in Germany were found by sailplane pilots to be forming in ascending currents of air and seem to have been the first really high clouds to be recognized as definitely orographic in origin.

Now Mr. F. H. Ludlam, a colleague of Dr. Scorer, claims in the October 1952 issues of *Weather* and the *Quarterly Journal of the Royal Meteorological Society* that some of the cirrus cloud seen over England at heights as great as 20,000 ft. or more is produced in orographic waves. He believes orographic cirrus forms as water particles at a temperature of about – 40° C. The drops soon freeze, and are carried downwind as a trail of ice crystals. Making observations from Dunstable, Bedfordshire, of the azimuth and elevation of the initial points of some cirrus trails and taking the height from the – 40° C.-level in the Meteorological Office upper-air temperature readings, he has been able to relate these initial points to prominent hills such as the Black Mountains, the Long Mynd, Cleeve Hill and the Peak, some of them more than a hundred miles from Dunstable. Sometimes a number of cirrus trails, all at the same height, could be seen streaming each from above the hill responsible for it. A further height check made with good results was a comparison of the movement of details of the trails with the official upper wind observations. In support of his idea he points out that aircraft pilots have observed up and down currents of several metres per second at 10,000–30,000 ft. over the low English hills. Further, the cirrus formation diminishes in the afternoon in accordance with Dr. Scorer's theory of wave formation.

Mr. Ludlam's ingenious and picturesque ideas are not yet accepted by all meteorologists. However, they promise to add a new pleasure to cloud observing—finding the hill over which a cirrus trail begins.

HETEROGENEITY OF DEOXYRIBONUCLEIC ACIDS

By DR. GEOFFREY L. BROWN and M. WATSON

Medical Research Council Biophysics Research Unit,
Wheatstone Physics Laboratory, King's College, London,
W.C.2

THE current belief that deoxyribonucleic acids are intimately concerned in the maintenance and transmission of genetic specificity, for which there is a considerable amount of evidence, leads to the suggestion that preparations of this material may possibly consist of a large number of molecular species differing very slightly from each other in some respect. Chargaff and his collaborators[1] and Wyatt[2] have analysed many deoxyribonucleic preparations with regard to their content of purine and pyrimidine bases, and have found that preparations isolated from the same species have a constant composition, whereas the compositions of preparations from different species vary considerably. There are then three evident ways in which specific differences can be carried by the deoxyribonucleic acid of one species. Either it contains a number of molecules with different sequences of bases along the polynucleotide chains but all with the same base constitution, or it consists of molecules of different composition with a distribution of base ratios characteristic of the species. The third possibility, that specific folding of the polynucleotide chain may occur, has been ruled out by the X-ray diffraction studies of Wilkins and his collaborators[3] on deoxyribonucleic acids from different species, which show a helical structure independent of the base constitution. Less probable molecular differences that might form the basis of genetic specificity are the length of the polynucleotide chain and degree of polymerization[4]. The object of the work to be described was to devise a chromatographic or similar technique for separating deoxyribonucleic acids from each other using their interaction with histone, a protein with which they are closely associated in cells and with which they might be expected to interact in a specific manner.

Histone, purified from calf thymus according to Daly, Mirsky and Ris[5], was immobilized on the surface of kieselguhr by a method to be described in detail later. The histone-coated kieselguhr stains with acidic dyes and adsorbs deoxyribonucleic acids from 0·1 *M* sodium chloride solutions. The experimental procedure used was as follows. The kieselguhr was dispersed in 0·4 *M* sodium chloride and columns formed in 1·0-cm. diameter tubes; the deoxyribonucleic acid solutions at suitable concentrations were added to the top of the column and washed into the column under pressure, where they were adsorbed. The material could then be eluted by stronger salt solutions, either with stepwise increases in salt concentration or with continuously increasing salt concentrations. 2-ml. fractions were collected on automatic fraction collectors and the deoxyribonucleic acid content of the fractions estimated by their optical density at 260 mμ. A typical stepwise elution diagram of calf thymus deoxyribonucleic acid prepared according to Schwander and Signer[6] is shown in Fig. 1. This shows clearly that with each increase in salt concentration a definite fraction of the deoxyribonucleic acid is eluted sharply at the concentration boundary between one eluting solution and the preceding one, demonstrating that the preparation is heterogeneous with respect to the strength of the salt linkages binding the acid to the basic protein. Fig. 2, curve *b*, shows an elution diagram of the same calf thymus preparation obtained by slowly increasing the concentration of the eluting salt solution to 0·8 *M*. From this it would seem that the preparation is highly polydisperse with regard to these binding properties. Fractionations were also made using larger columns with correspondingly heavier loadings of deoxyribonucleic acid, and the fractions were analysed for their content of purines and pyrimidines by the method of Wyatt[7]. These results are shown in the accompanying table. The analyses demonstrate clearly that the ratios of adenine to guanine and thymine to cytosine of a fraction increase as the salt concentration needed to elute them from the column increases.

BASE ANALYSES* OF FRACTIONS OBTAINED FROM CALF THYMUS DEOXYRIBONUCLEIC ACID

Fraction No.	I	II	III	IV	V	Unfractionated calf thymus DNA
Eluting molarities of sodium chloride	0·4– 0·54	0·54– 0·61	0·61– 0·70	0·70– 0·79	0·79– 0·9	
Guanine	22·8	19·7	19·5	19·3	16·1	21·5
Adenine	25·8	28·5	29·3	29·8	33·9	28·2
Cytosine	24·0	22·4	19·8	21·3	19·7	21·3
Thymine	27·4	29·4	31·4	29·6	30·3	27·8
Adenine/Guanine	1·13	1·45	1·5	1·54	2·1	1·31
Thymine/Cytosine	1·14	1·31	1·58	1·39	1·54	1·34

* Expressed as percentages of total bases

That the intact structure of the deoxyribonucleic acid is necessary for the binding to histone to be effective and not just a polynucleotide chain is clearly demonstrated by the results shown in Fig. 3. Fig. 3 (*a*) shows that yeast ribonucleic acid is eluted by 0·4 *M* sodium chloride and is not retained by the column as deoxyribonucleic acid. This observation provides a simple and rapid method for the removal of contaminating ribonucleic acid from preparations of deoxyribonucleic acid. Fig. 3′(*b*) shows the complete elution of deoxyribonucleic acid from a column with 0·4 *M* sodium chloride after having been heated at 100° C. for 30 min. in neutral solution. This treatment presumably breaks down the helical structure of the polynucleotide so that the specific binding observed above no longer occurs.

Fig. 2 shows the effect of species difference on the elution diagram of deoxyribonucleic acid. The deoxyribonucleic acid of *E. coli*, type *B*, was prepared according to Gandelman *et al.*[8], except that ribonucleic acid was removed by eluting with 0·4 *M* sodium chloride, as described above, instead of using 'Norit' to adsorb it, and the elution diagram shown in Fig. 2, curve *a*, was obtained. Curve *b* shows a calf thymus deoxyribonucleic acid diagram for comparison and curve *c* an elution diagram of a deoxyribonucleic acid prepared from human white blood

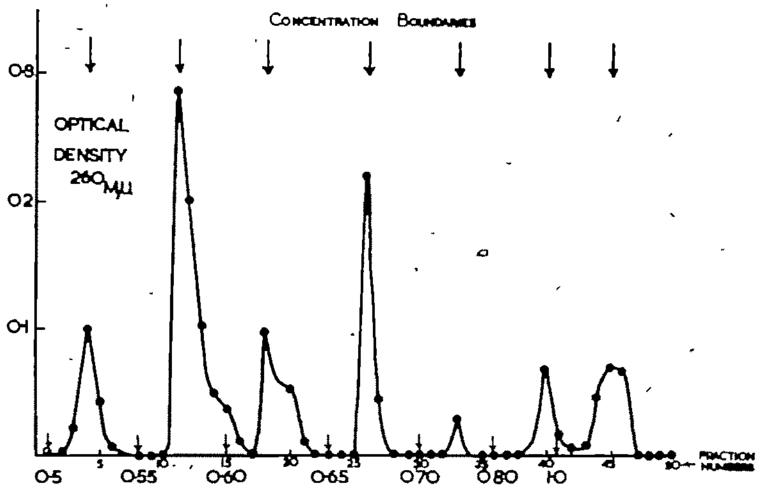

Fig. 1. Stepwise elution of calf-thymus deoxyribonucleic acid from a column of histone-coated kieselguhr with solutions of sodium chloride

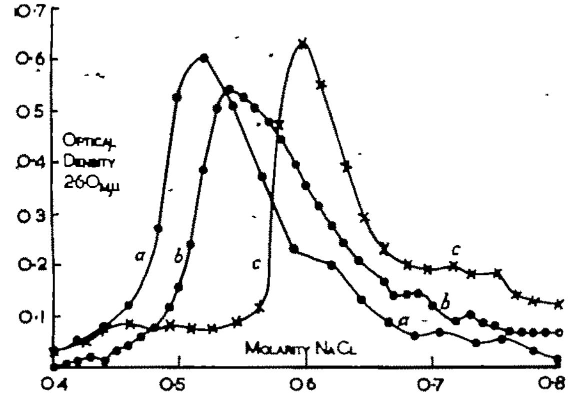

Fig. 2. Elution diagrams of some deoxyribonucleic acids obtained by eluting with continuously increasing salt solutions
Curve *a*, —●—●—●—, deoxyribonucleic acid from *E. coli*, type *B*; curve *b*, —○—○—○—, deoxyribonucleic acid from calf thymus; curve *c*, —×—×—×—, deoxyribonucleic acid from human white blood cells

cells. The ratios of adenine to guanine for these three species have been measured as 1·05, 1·29 and 1·56 and the thymine to cytosine ratios as 0·95, 1·43 and 1·75, respectively[1], and it can be seen from Fig. 2 that the elution peaks are displaced along the salt axis relative to each other in the same order as these ratios. This is further confirmation of the observations made on the calf thymus deoxyribonucleic acid that the ratios of the bases in a fraction vary with the salt concentration needed to dissociate the fraction from the bound histone.

While the work described above was nearing completion, Prof. E. Chargaff and his collaborators generously made available to us their extensive analytical results on extracts of deoxyribonucleic acid from calf thymus nucleohistone using various salt concentrations, which show a similar variation of base ratios with the salt needed to extract the fractions[9]. In our opinion, their results and ours demonstrate that the deoxyribonucleic acid of a particular species consists of a continuous distribution of molecular species with varying ratios of the bases, and that the binding of these molecular species to histone increases as the ratios of adenine to guanine and thymine to cytosine increases. Bendich[10] has observed that deoxyribonucleic acid preparations obtained by extraction of tissues at 85° C. were heterogeneous with respect to solubility in dilute salt solutions and to the metabolism of the purine and pyrimidine bases.

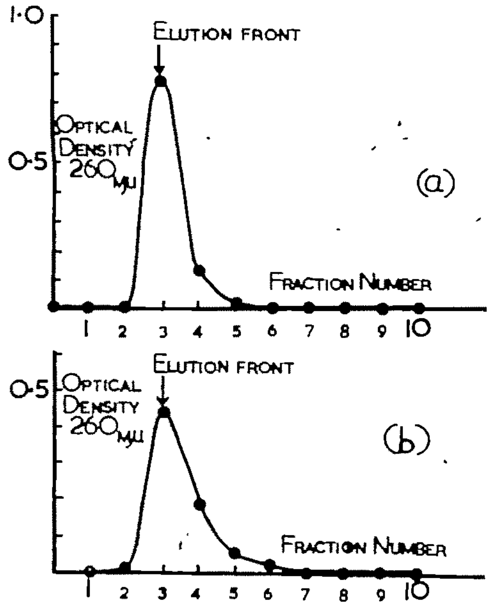

Fig. 3. (*a*) Elution of yeast ribonucleic acid from a histone-coated kieselguhr column with 0·4 *M* sodium chloride. (*b*) Elution of calf thymus deoxyribonucleic acid heated at 100° C. for 30 min. from a histone-coated kieselguhr column with 0·4 *M* sodium chloride

In view of the recent advances in our knowledge about the structure of the deoxyribonucleic acid molecule, it is of interest to consider a possible structural basis for the variation of the strength of the binding to histone, and we wish to put forward tentatively the following explanation. The work of Cavalieri[10] on the spectrophotometric titration of deoxyribonucleic acid with acids and magnesium ions indicates that some of the bases may be bonded to phosphate groups in the molecule. The X-ray diffraction studies of Wilkins, Franklin and their collaborators[11,12] demonstrate that deoxyribonucleic acids have a helical structure with the sugar-phosphate backbone on the outside and the bases pointing inwards. On examination of helical polynucleotide chains, it is evident that with certain types of helical arrangements the 2-amino group of guanine can approach near enough to a phosphate group in the sugar–phosphate backbone to form a hydrogen bond of the type[13] P=O—H—N. The existence of this type of bonding is supported by the infra-red work of Fraser and Fraser[14], who assigned a band in the infra-red to P=O—H. The bonding of an amino group to a phosphate group in this way might be expected to reduce the acidic properties of the phosphate in question, and therefore to reduce the concentration of sodium chloride needed to dissociate the salt linkage that it can form with a basic group in histone.

Therefore, if these ideas are correct, the higher the guanine content of a deoxyribonucleic acid the lower the salt concentration that should be necessary to dissociate it from histone. This is exactly what is found in the experiments described above and by Chargaff and his collaborators in their fractionation experiments. Cavalieri interprets his experiments on the interaction of positively charged dyes with deoxyribonucleic acid[15] as indicating a heterogeneity of binding strengths of the phosphate groups for the dyes which would be expected if the ideas put forward above are correct. Also, his experiments using an equilibrium dialysis technique and spectrophotometric titration show that, first, about ·1 mole of magnesium ions per 5 moles phosphorus is bound to calf thymus deoxyribonucleic acid and, secondly, that magnesium probably forms a chelated complex between an amino group and a phosphate group. On the basis of the previous discussion, it seems very likely that again the 2-amino group of guanine is involved, especially as the mole fraction of guanine to total bases is 0·21 in calf thymus deoxyribonucleic acid. We would like to suggest, then, that magnesium and similar ions can form a chelate bridge between the 2-amino group of guanine and a neighbouring phosphate group, the hydrogen bond being broken in the presence of magnesium, thus producing the changes of absorption in the ultra-violet spectrum on addition of this ion, as observed by Cavalieri and verified in this laboratory[16].

All the above evidence for some kind of linkage between the 2-amino group of guanine and a phosphate group in the helical backbone is very circumstantial; but the discovery of fractional dissociation of deoxyribonucleic acid observed by Chargaff and his collaborators, and in the experiments described above, and its correlation with guanine content, adds considerable point to that evidence. If further experiments support the idea, it will provide a structural basis for specific interactions between the helical sugar–phosphate backbone of deoxyribonucleic acid and basic proteins which will be determined by the position of guanine in the sequence of purines and pyrimidines.

We are much indebted to Prof. J. T. Randall for his advice and encouragement; to Prof. E. Chargaff for making his results available to us prior to publication and for discussion; to Dr. M. H. F. Wilkins, Dr. W. E. Seeds and Dr. R. H. Smith for useful discussions. We thank also Dr. L. Hamilton and Dr. R. Barclay for a sample of human deoxyribonucleic acid. [July 7.

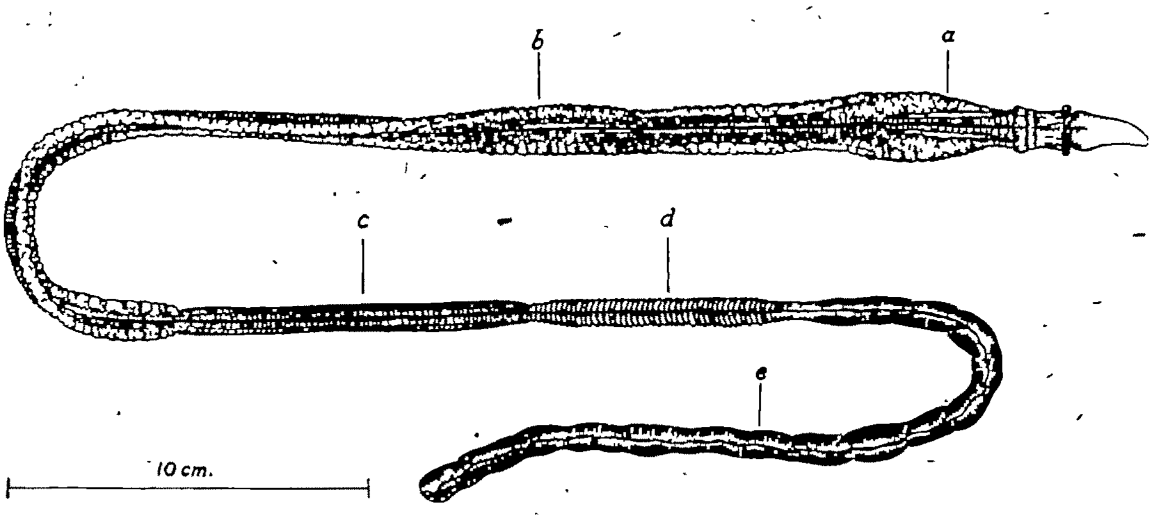
RECORDS OF BRITISH PTYCHODERIDÆ

THE records of the occurrence of the Ptychoderidæ around the coasts of the British Isles are few. A fragment of a *Balanoglossus* has been found on the coast of Galway[1] and an incomplete specimen of *Glossobalanus marginatus* Meek has been dredged off the Northumberland coast[2]. Otherwise the only indication of their presence has been the frequent occurrence of tornaria larvæ[3]. Since these larvæ are planktotrophic for several weeks[4], it has long been supposed that the adults occurred in British waters. Stiasny-Wijnhoff and Stiasny studied numerous tornaria larvæ from British and adjacent waters and concluded that they belonged to one or other of the following species: *Glossobalanus marginatus* Meek, *G. sarniensis* Köehler, or *Balanoglossus clavigerus* Del Chiaje. They were certain of their identification of the larvæ of *Balanoglossus clavigerus*, but speculated on the probable origin of the others.

Since the discovery of *Glossobalanus marginatus*, several species of Harrimanidæ have been recorded (for references see footnote 5), but hitherto none of the Ptychoderidæ. However, since my work on this group began, numerous specimens of a *Glossobalanus* species have been submitted to me for examination. In all, some forty-four specimens have been collected; of these, five were found in Salcombe Harbour by Dr. D. P. Wilson and students, three were dredged south of the Eddystone Lighthouse by Dr. N. Holme[6] (Plymouth), four at Portaferry, Co. Down, Northern Ireland, by Mr. C. Edwards[7], and the remainder were found by Miss M. Green (Castlecove, Killarney) and the late Dr. Stanley Kemp (Plymouth) in the Kenmare Estuary, Southern Ireland. These specimens were compared with material I collected in the Skagerrak, and with specimens from the British Museum (Natural History). They were all identified as *Glossobalanus sarniensis* Köehler; but the incompleteness of the existing literature made this difficult, and in consequence a revised description is being prepared for publication.

Previous workers had to rely on incomplete material, so the hepatic region has never been accurately described; yet its form was a deciding factor in the identification of this species. The hepatic sacculæ were dorsally placed in a regular paired series. The number of pairs varied from forty-five to fifty in the specimens examined, and may be exceeded in larger specimens. The genital wings do not overlap the sacculated hepatic region, but are separated from it by a long thin-walled transitional region, and its fragility was probably responsible for the incom-



Glossobalanus sarniensis. A reconstruction based on several specimens. *a*, branchial region; *b*, genital region; *c*, transitional region; *d*, hepatic region; *e*, intestinal region pleteness of material hitherto described. Most specimens examined were broken at the junction of the genital and transitional regions. The post-hepatic regions were more robust and are well figured by Köehler[8]. The accompanying drawing is a reconstruction based on several specimens showing the hepatic region in its correct form. Sectioned material revealed that the dorsal diverticulum of the buccal cavity had two latero-ventrally placed diverticulæ proximally, the lumina of which remained distinct from that of the main one, but tended to become confluent posteriorly.

All the specimens were found in muddy sand with some admixture of shell gravel. A few of the Kenmare specimens were found in comparatively clean sand and shell gravel. The shores which yielded these specimens were subjected to a good tidal flow without undue turbulence, for in all cases the areas were sheltered from surf action. Adjacent *Zostera* beds or dense algal growth provided an abundance of detritus upon which the enteropneusts could feed[5,9,10].

The associated fauna was in many respects typical of sandy mud, and included *Echino-cardium cordatum* (Pennant), *Acrocnida brachiata* (Montagu), *Leptosynapta inhærens* (O. F. Müller), *Labidoplax digitata* (Montagu), *Upogebia deltaura* (Leach), *Arenicola marina* L., *Amphitrite johnstoni* (Malmgren), *Cerianthus lloydi* (Gosse), *Chætopterus variopedatus* Renier, and numerous bivalves.

The specimens collected on the shore were found between mean low-water springs, and in many instances involved a considerable amount of deep digging. Their burrows often extended from twelve to fifteen inches into the substratum. For an account of the fauna and flora of the Small's Cove and Mill Bay area from which the Salcombe specimens were collected see Wilson[11].

Although many enteropneusts are gregarious animals, and solitary specimens may be strays from a colony near by, the prolonged planktotrophic life of the tornaria undoubtedly results in a wide scattering of individual specimens. *Glossobalanus marginatus* and *G. sarniensis* are both common in the Skagerrak[12], the former favouring muddier areas and deeper water than the latter, and it is very probable that they are also widely distributed throughout the North Sea. The Baltic Stream and cyclic currents of the North Sea would assist in their dispersal. The frequent occurrence of *Tornaria mielcki* and *T. bournei* in this area tends to substantiate this. From collections of adults made in the Skagerrak, and tornaria examined from various parts of the North Sea, it seems that *G. marginatus* is the dominant species, whereas tornaria collected from the Plymouth area and other points in the Celtic Sea indicate that *G. sarniensis* and *Balanoglossus clavigerus* are the dominant species in the English Channel and more southern British waters. Both species have been recorded from the coast of Brittany. Of these species, *Balanoglossus clavigerus* alone penetrates into the Mediterranean Sea, whereas the abundance of *T. bournei* in the waters around the Scilly Isles suggests that *G. sarniensis* is likely to prove the dominant form in the Celtic Sea west of Penzance, and along the Atlantic coast of Ireland. The occurrence of *Tornaria bournei* at Port Erin coupled with the recent Portaferry discovery are strong indications that *G. sarniensis* may also be widely dispersed throughout the Irish Sea.

Thanks are due to all who have provided material or information relevant to the above, and especially to Mr. J. G. Cattley, of the Ministry of Agriculture and Fisheries at Lowestoft, for numerous tornaria, and to Miss M. Green and Dr. D. P. Wilson for much of the adult material.

Occurrence of the Enteropneust *Glossobalanus sarniensis* Köehler in Northern Ireland

PREVIOUS records of adult Ptychoderidæ in British waters are extremely few, despite the widespread occurrence of tornaria larvæ. However, Burdon-Jones[1] reports the occurrence of adults in several localities, and it is of interest to record the recent finding of *Glossobalanus sarniensis* Köehler in Northern Ireland.

Four examples of this species were taken in September and October 1952, at Portaferry, Co. Down, at the narrow entrance to Strangford Lough. They were obtained between the levels of mean and extreme low-water springs in a restricted area of somewhat muddy sand with a substratum of shell gravel. The area is subject to great tidal change of water but with little turbulence, and is adjacent to shores densely covered with weed. These conditions provide an abundance of detritus, as is evidenced by the varied fauna occurring with the enteropneust. Species found commonly or abundantly there include *Cerianthus lloydi* Gosse, *Sagartia elegans* (Dalyell), *Arenicola marina* L., *Amphitrite johnstoni* Malmgren, *Pectinaria belgica* (Pallas), *Ensis arcuatus* (Jeffreys), *Acrocnida brachiata* (Montagu), *Echinocardium cordatum* (Pennant), and *Leptosynapta inhærens* (O. F. Müller).

In view of its restricted intertidal area of occurrence and its sparseness there, it is probable that the main, and so far undetected, area occupied by the enteropneust lies below the tidal zone, and even in the Irish Sea, larvæ being probably brought into the lough with the tidal flow.

Spengel[2] figures the species as having a small egg-shaped proboscis, but admits that he was working with preserved material. Köehler[3] describes the proboscis as being conical in life. My specimens showed it in the resting condition in life to be approximately conical and bluntly pointed.

Nidulin and 'Ustin': Two Chlorine-containing Metabolic Products of *Aspergillus nidulans*

A mould, isolated by Kurung[1] in 1944 and considered to be a strain of *Aspergillus ustus* (Bain.) Thom and Church, was shown to produce a metabolic liquor which possessed a marked antibiotic activity towards *Mycobacterium tuberculosis* and *M. ranae*. Afterwards, Hogeboom and Craig[2], by application of a counter-current technique, were able to isolate, from an ethereal extract of this mould and its substrate, two crystalline products, called compound I and compound II, which showed a very high activity against *M. ranae*. Doering, Dubos, Noyce and Dreyfus[3], using the same strain of mould, isolated a number of chlorine-containing metabolic products, one of which was proved to be identical with Hogeboom and Craig's compound I. Doering *et al.* proposed the name 'ustin' for this compound, established its empirical formula ($C_{19}H_{14}O_5Cl_2$) and published a superficial account of some of its chemical properties.

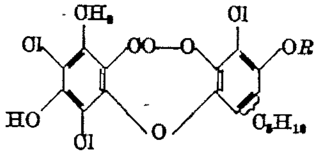
Kurung's original strain has now been examined more exhaustively, and we conclude that it is, in fact, a non-ascosporic strain of *Aspergillus nidulans*.

When this mould is grown at 30° C. on a medium containing Czapek–Dox salts, 4 per cent glucose and 0·1 per cent 'Marmite', some 'ustin' is produced in the substrate and much fatty material is to be found in the mycelium. However, when the mould is grown on the same substrate but at a much lower temperature, the amount of fat is considerably reduced and, from the dried mycelium, a crystalline compound for which we propose the name 'nidulin', can be isolated as the main product. The yield of this compound is very variable, but on one occasion it formed as much as 5 per cent of the dried mycelium.

Crude nidulin is deposited as a brownish crystalline mass when a light petroleum (boiling point 40–60° C.) extract of the dried and powdered mycelium is allowed to stand for six days. (A further quantity is obtainable by extracting the petroleum-extracted mycelium with ether and evaporating the solvent.) The crude product may be purified by successive crystallizations from ethanol (95 per cent) and from light petroleum (boiling point 60–70° C.). Pure nidulin, $C_{20}H_{17}O_5Cl_3$, crystallizes from ethanol in colourless rhombs and from light petroleum in slender, shining rods, melting point 180° C. (Found: C, 54·3; H, 4·0; Cl, 23·7; OMe, 6·9 per cent; equiv., by titration, 435; *M* (Micro-Rast), 463. $C_{19}H_{14}O_4Cl_3(OMe)$ requires C, 54·1; H, 3·9; Cl, 24·0; OMe, 7·0 per cent; *M*, 443·7.) Nidulin is insoluble in water, but soluble in aqueous solutions of sodium hydroxide and of sodium bicarbonate, easily soluble in chloroform, sparingly soluble in ethanol (95 per cent) and benzene and very sparingly soluble in hot light petroleum (boiling point 60–70° C.). A 4 per cent solution in chloroform shows no optical activity.

Nidulin has been shown to be the mono-methyl ether of 'ustin', and the chemistry of these compounds has been investigated in some detail. Since nidulin is, at least under certain specified conditions, the main metabolic product, and since also the mould is now considered to be a strain of *A. nidulans*, we suggest that the name 'ustin' be dropped and that Hogeboom and Craig's compound I or 'ustin' be now called '*nor*-nidulin'.

We suggest the following partial structures for nidulin and for *nor*-nidulin ('ustin'):



Nidulin ($R = CH_3$). *Nor*-nidulin or 'ustin' ($R = H$)

The antibiotic activity of nidulin has been investigated, through the courtesy of Dr. W. F. Short, by Messrs. Boots Pure Drug Co., Nottingham, to whom we are indebted for the following information. Nidulin completely inhibits the growth of *M. tuberculosis* for four weeks at a dilution of between 1 in 5,000 and 1 in 10,000; the test was carried out in presence of serum, by modified Long's medium and the floating-pellicle method. A 0·1 per cent solution also inhibits the growth of the human parasitic fungi *Trichophyton tonsurans* and *Microsporum audouini*, but shows little or no activity towards quite a wide range of other micro-organisms. It is inactive against bacteriophage. (For microbiological testing a solution of nidulin is made by dissolving a known quantity in a little warm ethanol, adding one equivalent of aqueous 0·1 *N* sodium hydroxide solution and diluting with water.)

Full details of the chemistry of nidulin will shortly be published elsewhere.

One of us (J. C. R.) wishes to thank the Leverhulme Trustees for the award of a research fellowship.

Biogenesis of Alkaloids of Solanaceæ

Thirty-six years ago[1] I directed attention to the structural relations between hygrine, cuskhygrine, tropine and other similar bases, and drew the conclusion that the units concerned in the biogenesis were ornithine or proline on one hand, and an acetone equivalent on the other. P. I. Mortimer[2] now advances a different hypothesis on the sole new ground that hyoscine and nicotine have been found to be congeneric in one instance at least[3].

This latter fact is of great interest; but it is in full accord with my early paper[1]. The matter will be developed from my own point of view in another place.

The arguments from configuration which Mr. Mortimer uses are not significant, because nobody can suppose that the pyrrolidine rings of the alkaloids arise 'directly' from L-proline. There could, and very probably would, be a racemization stage, and the stereoisomeride eventually produced would depend on the exigencies of the situation in the organism. There are several examples of the occurrence of alkaloids, among other natural products, in more than one stereoisomeric form in different plants.

Secondly, the actual mechanism proposed is based on the improbable assumption that the formation of nicotinic acid from tryptophan, admittedly proved in certain cases, indicates the path along which other β-substituted pyridines must have travelled.

It is not even certain that nicotinic acid itself is always produced from tryptophan. The mechanisms proposed by Mr. Mortimer are incomplete and in many places extremely unlikely, as, for example, in the suggestion that 3-hydroxyanthranilic acid might suffer oxidative fission between carbon atoms numbered 1 and 2.

Thirdly, I agree with Mr. Mortimer that the co-occurrences of tropane- and hygrine-type bases are of biogenetic significance, and have been saying this at intervals over a long period of years.

Finally, it is surely a weakness of Mr. Mortimer's hypothesis that, for this base alone, he is prepared to contemplate a reversion to the so-called 'classical scheme'.

There are many other reasons for rejecting Mr. Mortimer's suggestions; but I will only mention their inability to embrace the ring homologous bases (conine, pelletierines, lobelanine, etc.) in any acceptable manner. These piperidine alkaloids are clearly related to lysine (or piperidine-α-carboxylic acid) in the same way as the pyrrolidine alkaloids are related to ornithine (or proline).

Dissimilation of Citric Acid by Bacterial Extracts

Aerobacter aerogenes is able to utilize citric acid as sole source of carbon for growth, and from an analysis of fermentation liquors, Deffner and Franke[1] and Brewer and Werkman[2] concluded that citrate is dissimilated to oxaloacetate and acetate as initial products. Dagley and Dawes[3] have confirmed earlier observations on the adaptive nature of the dissimilating enzyme and have shown that cells have maximum activity when harvested from anaerobic media in which citric acid is limiting for growth: media used in the present work fulfil these conditions.

A. aerogenes was grown without aeration at 37° C. in 10-litre flasks filled to the neck with medium of the following composition: 9 gm. trisodium citrate.$2H_2O$; 2 gm. potassium dihydrogen phosphate; 1 gm. ammonium sulphate and 0·4 gm. magnesium sulphate.$7H_2O$ per litre adjusted to *p*H 7·0 with sodium hydroxide. After harvesting, 10 gm. of cell paste was crushed in a Hughes press[4] previously cooled on solid carbon dioxide, taken up in phosphate buffer and, after centrifugation at 7,000 *g*, 60 ml. of translucent cell-free extract was obtained. When 0·5 ml. of extract was incubated at 37° C. with 6 ml. of phosphate buffer (*p*H 7·0, 5 gm./lit. potassium dihydrogen phosphate, 0·4 gm./lit. magnesium sulphate.$7H_2O$) containing 6×10^{-4} *M* citric acid, the latter was completely converted to pyruvate within 10 min. In this period of time the extract showed negligible action on pyruvate; no measurable keto-acid production as determined by the method of Friedemann and Haugen[5] was given from malic, fumaric or succinic acids; but strong oxaloacetic decarboxylase activity was exhibited. Extracts could be stored in the frozen condition and remained active when thawed at intervals for use over a period of at least ten days. Evolution of carbon dioxide measured in a nitrogen atmosphere in the Warburg respirometer was linear in the initial 30 min., and initial rates were directly proportional to the volume of extract present. When the citrate concentration was varied and a fixed quantity of extract used, approximately 1 mol. of pyruvate was produced from each molecule of citrate up to a concentration of the latter of 6×10^{-4} *M*; at higher concentrations the rate of pyruvate production decreased after the initial rapid attainment of a concentration of 6×10^{-4} *M*, and citrate remained in excess even after prolonged incubation. Other instances of the toxic effect of keto-acids accumulating from the action of extracts have been reported[6].

The rate of total keto-acid production, and of pyruvic acid as estimated by the specific toluene extraction method[5], was reduced to one-sixth in the presence of 0·1 *M* sodium fluoride and suggested the participation of magnesium ions as coenzyme in citrate dissimilation in addition to their known role[7] in the enzymatic decarboxylation of oxaloacetate. When extracts were dialysed against water, keto-acid production was stimulated as follows:

	Time of incubation (min.)	Keto-acid produced (μgm./3 ml.) Pyruvate	Total keto-acid
Dialysed extract	20	6·0	8·0
,, ,, + $MgSO_4$	20	24·0	40·0
,, ,,	60	8·0	12·0
,, ,, + $MgSO_4$	60	30·0	30·0

Concentration of $MgSO_4$ $1{\cdot}66 \times 10^{-3}$ *M*.

No keto-acids were produced by extract in absence of citrate, with or without magnesium ions. Additions of manganese did not activate the system.

The nature of the keto-acids produced in the reaction was investigated by paper chromatography of the 2 : 4 dinitrophenylhydrazones by the procedure of Dagley, Fewster and Happold[8]. Production of pyruvate was readily demonstrated but oxaloacetate was not found in most cases; its speed of decomposition by extracts indicated that its accumulation was precluded. When frozen and stored, however, the oxaloacetic decarboxylase activity of extracts diminished. A well-defined spot corresponding to oxaloacetic acid appeared in addition to that for pyruvate when 0·04 *M* *dl*-malic acid, known to inhibit oxaloacetic decarboxylase[9], was present during incubation of citrate with these 'stored' extracts. These observations accord with the view that the steps in citrate dissimilation are: (1) citrate → oxaloacetate + acetate; (2) oxaloacetate → pyruvate + carbon dioxide. Estimations of acetic acid (by steam distillation) and of carbon dioxide (by respirometry) showed that approximately one molecule of each was formed per molecule of pyruvate produced, as reactions (1) and (2) require.

Reaction (1) is an apparent reversal of the synthesis of citrate from oxaloacetate and acetate, catalysed by extracts from *Esch. coli*[10]. This view is not supported, however, by our results[3] with whole cells, which indicate that the enzyme involved is adaptive and is suppressed by growth with aeration; extracts from cells so grown possess only feeble activity. Further, when active extracts were treated with 'Dowex-1' according to the method of Chantrenne and Lipmann[11] to remove coenzyme A, additions of the latter and of diphosphopyridine nucleotide had no effect on activity. It appears that citric acid may by synthesized by one biochemical route involving acetyl-coenzyme A and may be dissimilated in certain systems by another.

We express our thanks to Mrs. M. Lees and Mr. J. Smillie for their technical assistance, to Mr. R. Noble for a helpful discussion, to the Agricultural Research Council for grants for these laboratories and to the Carnegie Trust for a personal grant to one of us (E. A. D.) for apparatus.

A New Hydroxy-acid in the Peel of Apple Fruits

DURING the examination of paper chromatograms of extracts from whole mature Edward VII apples, a faint acid spot appeared which did not correspond in position with any of the usual fruit acids. On chromatograms of extracts of peel tissue only, the unknown acid appeared to be present in an amount approximately one-quarter that of the malic acid present (the chief acid present in the fruit). About half a gram of the unknown acid was isolated in the pure form from peel tissue extracts by means of silica gel chromatography[1], avoiding contact of the extracts with strongly basic ion-exchange resins during the process[2]. The acid crystallized with difficulty from water as needle-like crystals. Recrystallized from ether it gave a melting point of 94–96° C. On elementary analysis the acid proved to have a molecular formula corresponding to $C_5H_8O_5$ ($C = 41 \cdot 5$, $H = 5 \cdot 4$ per cent); its silver salt had a silver content of 58·5 per cent. The molecular weight (Rast) was found to be 148. The acid gave on analysis 9 per cent 'OH'; the hydroxyglutaric acids contain 11·5 per cent 'OH', but β-hydroxy-acids tend to lose water when treated with acetic anhydride, which would lead to low results in the determination of 'OH' groups. Solutions of the acid gave a positive Denigès test[3] after oxidation with potassium permanganate. These facts provide the basis for its provisional identification as either β-OH-glutaric acid or citramalic acid. Further details will be published elsewhere.

Purines in Grassland Herbage

THE non-protein nitrogenous fraction of grassland herbage usually represents 15–20 per cent of the total nitrogen[1] of the herbage. Since the fraction is frequently blamed, without supporting evidence, for causing ill-defined disturbances in animal health, it is obviously desirable to learn as much as possible about its constituents.

It is known that ammonia, nitrate, acid amides and amino-acids account for 50–60 per cent of the nitrogen of the fraction and their determination presents no difficulties; but the remainder has not been investigated in detail.

The fraction is receiving attention at Jealott's Hill using methods of paper and ion-exchange chromatography. A purine fraction has been separated which contains a mixture of several purines. Four purines have been identified almost certainly as adenine, guanine, xanthine and hypoxanthine, although the latter is not invariably present.

In most of the work herbage juice has been used, removing chloroplasts, protein, etc., by heat and alcohol treatments. The passage of the clarified juice through Zeo-Karb 215, followed by displacement of the bases by alkali, resulted in material coming out of solution in the column and this upset the regularity of displacement. Tests suggested that the insoluble material consisted of purines, and in subsequent work purines were removed from the clarified juice by precipitation with ammoniacal silver nitrate.

The purine fraction, after precipitation of silver with hydrochloric acid, was examined by paper chromatography. The paper when viewed in ultraviolet light (260 mμ) showed four spots which corresponded with the positions of pure adenine, guanine, xanthine and hypoxanthine. So far, it has not been possible to elute the spots and determine the quantities of the individual purines by ultraviolet absorption since the salts and foreign matter present cause tailing of the spots.

Further purification and separation have been effected by passing the solution of purines, in 2 *N* acid, through a Zeo-Karb 216 column and eluting with 2 *N* acid. Examination by ultra-violet absorption of the fractions collected showed the presence of the four purines; but considerable overlapping occurred. Using the fractions showing greatest absorption, absorption curves and maxima were obtained which correspond closely with those quoted by Cavalieri *et al.*[1] for the purines mentioned above.

If the purines could be eluted separately from an acid resin column, their quantitative determination would be relatively simple. Several workers[1-3] have attained complete separation of adenine and guanine; but, so far, we have failed to avoid marked overlapping when four purines are present.

The presence of four purines in grassland plants is of interest and, so far as is known, has not been reported previously. It seems likely that they exist in the free state, although enzymic breakdown of nucleosides, etc., during extraction of the plant juice cannot be ruled out.

It might be mentioned that when herbage juice is passed through a Zeo-Karb 215 column at least two substances absorbing ultra-violet light at 260 mμ pass rapidly through. Paper chromatography suggests these include the pyrimidines, thymine and uracil.

Some Effects of Mosaic Virus on Nitrogen and Phosphorus Metabolism in Tobacco Plants

EXPERIMENTS to determine the effects of infection with tobacco mosaic virus (Johnson's No. 1) on the nitrogen and phosphorus metabolism of tobacco leaves were made with a hundred plants grown in sand culture. Fifty plants when at the 8-leaf stage were infected artificially with pure virus. Groups of these and of the corresponding control plants were harvested 17, 27 and 40 days after infection.

Analyses of the leaves (from which midribs were excised) revealed that the concentrations of protein nitrogen and protein phosphorus (expressed as gm. per 100 gm. dry matter) were higher in leaves of infected plants than in those of the healthy control plants. The growth-rate of infected plants was lower than that of healthy controls, and this offset the higher concentration of protein nitrogen, with the result that the total protein nitrogen per plant was slightly lower in infected plants.

The concentration of protein phosphorus was higher in infected than in healthy plants throughout the forty-day growing period. In the healthy plants it decreased by 40 per cent during the period of observation, whereas in infected plants it remained constant. The total amount of protein phosphorus increased from 2·6 to 9·3 mgm. per plant in both healthy and infected plants after seventeen days; but thereafter the amount in the healthy plants remained sensibly constant while the total increased to 11 mgm. in the infected plants.

The virus content of homogenates of infected leaves as determined by the primary lesion method, described by Best[1], using a solution of known virus content[2] as reference standard, revealed that the virus formed an increasingly large proportion of the total protein of older leaves as infection proceeded, but constituted a roughly constant proportion of the protein of younger leaves.

The nitrogen–phosphorus ratio of the protein in the healthy leaves fell from 112 to 69 in forty days, whereas that of infected leaves fell to 54. This kind of difference would be expected because the virus nucleoprotein itself has a nitrogen–phosphorus ratio of 32. If we assume that the whole of the difference in the nitrogen–phosphorus ratio between healthy and infected plants is due to the presence of virus in the latter, we can calculate the weight of virus present. Values calculated in this way were in most cases higher than those obtained by the infectivity method. In young leaves only about one-quarter of the calculated 'total virus' was infective. In older mature leaves the proportion of infective virus was higher; but it decreased with duration of infection. The calculated total virus per plant continued to increase linearly with time throughout the growth period, whereas infective virus reached an apparent maximum after twenty-seven days. Our conclusions are consistent with those published by Bawden and Pirie[3].

The difference between amounts of 'total' and infective virus could be explained as being partly due to some infective virus having become inactive (older leaves), and partly to the presence of a non-infective pre-virus stage (young leaves).

All the above relates to plants grown with adequate nutrients. In a parallel series of plants grown under the same conditions but with nitrogen at a level which limited growth, the dry weight after seventeen days was 80 per cent, and after forty days 56 per cent, of that of the plants which had received adequate nitrogen. Although the plants with adequate nitrogen yielded a higher dry weight than the plants receiving inadequate nitrogen by a factor of 1·8, the amount of infective virus per plant was greater by a factor of 12 at the first harvest and 8 at the last harvest. On a concentration basis (gm. virus per 100 gm. dry matter) the factor was 11 and 5 respectively on the whole plant. When top and bottom leaves were analysed separately, the difference between the two nitrogen treatments was much greater in the bottom leaves than in the top leaves, the factors being 19 and 5 respectively. It would appear that when nitrogen is a limiting factor, the production of normal plant proteins is affected less than the production of virus.

A full account of this work will be published elsewhere.

Conversion of Plant Nitrogen to Microbial Nitrogen in the Rumen of the Sheep

PLANT protein in the fodder of ruminants does not arrive unaltered at the abomasum where peptic digestion takes place; there can be no doubt that at least a part of it is degraded, and later resynthesized to microbial protein by the enormous numbers of bacteria and other micro-organisms in the rumen. From time to time attempts have been made, usually on a basis of insufficient data, to calculate the extent of this conversion, and the estimates have varied from almost negligible proportions to 100 per

Table 1. NITROGEN AND LIGNIN IN THE FODDER AND RUMEN CONTENTS OF A SHEEP

		Nitrogen (mgm./100 gm.)			Nitrogen (mgm./gm. lignin) in rumen contents or in fodder†		
		Protein N	NPN*	Total N	Protein N	NPN	Total N
Rumen contents	Plant residues	62	10	72	42	7	49
	Micro-organisms	87	5	92	59	3	62
	Residual liquid	3	25	28	2	17	19
	Total	152	40	192	103	27	130
Fodder (wheaten hay)		870	240	1,110	107	30	137

* Phosphotungstic acid was used to precipitate proteins: boiling water extracts were employed in NPN determinations on fodders and plant residues.

† The fodder contained 8·1 per cent and the rumen contents 1·48 per cent lignin.

cent conversion[1]. Two more recent attempts[2] have involved the feeding of special proteins—zein and casein. No data are as yet available, however, which allow an accurate estimate to be made of the extent to which this conversion takes place in animals fed on natural fodders. In the course of certain studies of the functions of the omasum in the ruminant stomach (to be published elsewhere) we have had occasion to examine the distribution of nitrogen in the rumen contents of slaughtered sheep which had previously been fed on wheaten hay, and some of the results, together with analyses of the fodders, provide interesting information on the quantitative aspect of the conversion of plant to microbial nitrogenous compounds.

In Table 1 analyses of nitrogen and lignin in the fodder and rumen contents of one sheep are given in detail, and Table 2 presents a summary of the findings in seven animals. The solid and liquid portions of the rumen contents were separated by squeezing the material through muslin and washing the residual solids with water. The lignin content of the solids was determined by the method of Norman and Jenkins[3]. The liquid portion was separated into micro-organisms and residual liquid by centrifuging at 15,000 r.p.m. (17,000 *g*) for 30 min. Nitrogen determinations were made by the Kjeldahl method. Since lignin is not digested by sheep[4], the nitrogen concentrations in the fodder and rumen contents have been expressed as mgm. nitrogen/gm. lignin, so that a direct view of the extent of conversion of plant to microbial nitrogen, at the time of slaughtering, is available. Thus, in the example given in Table 1, 48 per cent of the total nitrogen of the rumen contents was present as microbial nitrogen, and (from Table 2) animals slaughtered at 2½, 3, 4, 8 and 16 hr. after the end of the feeding period all indicated that approximately 50 per cent of the nitrogen was microbial nitrogen. Furthermore, the fact that the concentration of total nitrogen, in terms of lignin (mgm. nitrogen/gm. lignin), was at all times nearly the same in the rumen as in the fodder, points to the conclusion that there was no significant overall gain or loss of nitrogen from the rumen other than by passage of the whole contents to lower levels of the alimentary tract. With certain fodders there may be significant losses of nitrogen by absorption of ammonia; but with wheaten hay this is apparently not the case. It may therefore be claimed that, when wheaten hay is fed to sheep, there is a conversion of about half of the plant nitrogen to microbial nitrogen in the rumen.

Table 2. NITROGEN IN THE RUMEN CONTENTS OF SLAUGHTERED SHEEP PREVIOUSLY FED ON CHAFFED WHEATEN HAY*

Sheep No.	Time after end of feeding period (hr.)	Nitrogen in rumen contents (mgm. N/gm. lignin in whole contents)				Nitrogen of rumen contents present as microbial nitrogen (per cent)
		Plant residues	Micro-organisms	Residual liquid	Total	
1	2½	49	62	19	130	48
2	3	43	65	17	125	52
3	4	62	78	8	148	53
4	4	63	66	7	136	49
5	4	75	69	8	152	45
6	8	67	85	12	164	52
7	16	51	76	14	141	54

* Fodder contained 1·11 per cent nitrogen and 8·1 per cent lignin—nitrogen = 137 mgm./gm. lignin.

These findings emphasize the important influence exerted by the rumen micro-organisms on the nature of the protein which finally becomes available to the host. They point also to the necessity for similar quantitative studies to be made of the extent to which the proteins in other plant fodders and concentrates are modified in the rumen, and thus to illuminate further the overall nutritional problems implied. Investigation of the amino-acid composition of the microbial protein synthesized in the rumen is undoubtedly of prime importance.

Effect of Cholinesterase Inhibitors and Atropine on Active Sodium Transport across Frog Skin

RECENT experiments have shown that compounds which affect acetylcholine metabolism can modify ion movement in a variety of tissues[1]. The locus of such drug effects can be better defined in the isolated frog skin, where it is possible to study quantitatively the active transport of sodium ions[2].

The anticholinesterase tetraethylpyrophosphate inhibits transport of sodium ions completely when added to the inside of the skin. Fig. 1 shows that there is a transient rise in the net flux of sodium ions (that is, inflow minus outflow) followed by an inhibition which is virtually complete in an hour. Inhibition was usually irreversible, although occasionally there occurred a slow, partial recovery. At the same time the diffusion resistance (electrical D.C. resistance) increased markedly. This seemed to

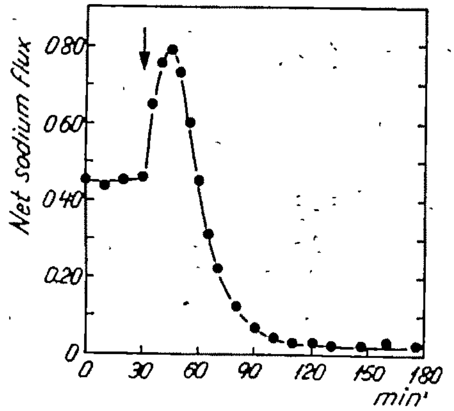

Fig. 1. Effect of tetraethylpyrophosphate on the active transport of sodium ions. The drug was added at the arrow to a concentration of 6×10^{-4} *M*. The net flux is in μM per cm.^{2} of skin per hr.

indicate that the skin was not structurally damaged. Another anticholinesterase, physostigmine (eserine), also inhibited the active transport of sodium ions. In this case, however, inhibition was reversible.

When applied to the outside of the skin, eserine was ineffective in concentrations less than 10^{-4} *M* and only slightly inhibitory at higher concentrations. Tetraethylpyrophosphate, in concentrations greater than 10^{-4} *M*, stopped the net movement of sodium ions; but the diffusion resistance dropped to a value approaching that of Ringer solution, which seemed to show that structural damage ensued.

When the outside of the skin was exposed to atropine, there was a marked increase in transport of sodium ions. Fig. 2 shows the results of an experiment in which atropine was added at the first arrow; when a new steady state was attained, the drug concentration was increased. In general, the flux increased as some non-linear function of the drug concentration, and the effect was sustained as long as the drug remained in the bath. It was reversed on washing with Ringer solution.

These experiments were performed on the skin of *Rana esculenta*. A few measurements with *R. temporaria* showed that the effect of tetraethylpyrophosphate could be repeated; but atropine did not cause stimulation.

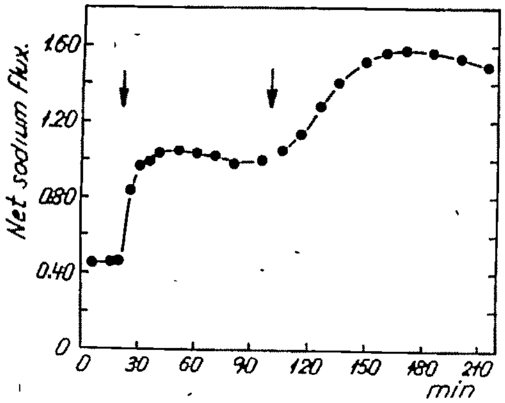

Fig. 2. Effect of atropine on the active transport of sodium ions. Atropine was added at the first arrow to a concentration of $2 \cdot 8 \times 10^{-5}$ *M*; concentration was increased to $1 \cdot 6 \times 10^{-4}$ *M* at the second arrow

The 'atropine effect' can, in fact, be induced by a series of pharmacologically diverse drugs, among them several curares, histamine and pilocarpine. Acetylcholine itself has little effect on the outside of the skin; hence it is very unlikely that the response to atropine involves the well-known competition between these two compounds. The action of the anticholinesterases, on the other hand, seems to parallel their activities as enzyme inhibitors. Three have been tested (tetraethylpyrophosphate, eserine and procaine) and their effects are nearly identical, although they have in common only their anti-esterase activities. The reversibility of the eserine inhibition and the irreversibility of the effect of tetraethylpyrophosphate are parallel to their properties as enzyme inhibitors.

Secretion of an Orthodiphenol in the Corpus Cardiacum of the Insect

ALTHOUGH it has been known for some years that the corpus cardiacum of insects contains a chromatophorotropic principle active on the chromatophores of many Crustacea[1], there has been very little information on the functions of the gland in the insect itself. It was interesting, therefore, to observe an effect of corpus cardiacum extract on the heart and gut of the insect.

Most of the observations have been made on the cockroach, *Periplaneta americana*. If the heart is prepared as described by Krijgsman and Krijgsman-Berger[2] and perfused with a suitable Ringer solution, it beats steadily for hours. A Ringer solution containing the aqueous extract of one pair of corpora cardiaca of the cockroach in each 10 ml. of solution causes an increase in the frequency of beat of some 50 per cent above normal. The amplitude of beat is also increased. At concentrations one-tenth as great an effect on the frequency cannot be observed; but the amplitude is still affected. These effects continue as long as perfusion with extract goes on, and the heart returns to normal very soon after the extract is replaced by normal Ringer solution.

The gut of the cockroach and of the locust, *Locusta migratoria*, will record peristaltic movements on a kymograph drum for at least twenty-four hours if perfused with the Ringer solution developed by Griffiths and Tauber[3]. An extract of one pair of corpora cardiaca to 10 ml. solution causes the rate of peristalsis in the hind-gut of the locust to be doubled, and stronger solutions have more marked effects. The hind-gut of *Periplaneta* behaves in the same way, but the peristalsis of the foregut seems to be inhibited by extracts of the gland. It is certain, also, in the locust that the increase in peristalsis of the Malpighian tubes observed by Koller[4] is due to a substance from the corpus cardiacum as well as from the brain. Boiling has no effect on the extract.

The corpus cardiacum gives a positive response to Lison's chromaffine test for orthodiphenols[5]. The extraction procedure of von Euler[6] for adrenaline was carried out on *Tenebrio molitor* larvæ, and the extract developed on paper chromatograms with somewhat different results from those of Gregerman and Wald[7]. If the brei is extracted quickly, instead of standing overnight in the refrigerator, a third spot is developed between R_F 0·3 and 0·4. This spot, if eluted, has the activity of corpus cardiacum extract; the other spots have not. A similar spot from a cockroach preparation has been shown to be due to the active substance from the corpus cardiacum. This position does not correspond to that of adrenaline on the paper chromatogram.

Attempts to compare the chromatophorotropic activity of this eluted material with crude corpus cardiacum extract, by injection into the prawn *Leander squilla*, have so far been quite inconclusive.

It is concluded, from the above results, that insects do not secrete adrenaline, but another orthodiphenol having the functions of adrenaline in the insect body.

The nerve connexions of the gland with the brain have been severed and the gland tested for activity after five and seventeen days. No change in activity was detected. It is likely, then, that the material is secreted in the gland itself and not in the neurosecretory cells of the brain[8].

This work has been aided by grants from the British Council and the National Research Council of Canada.

Action of Gamma-Rays on Seeds of *Cannabis sativa* L.

The differential sensitivity of certain chromosomic zones to ionizing radiations is a problem of theoretical and practical importance. Müller[1] and Kaufmann[2] reported a higher sensitivity to X-rays for heterochromatin *X* of salivary gland chromosomes of *Drosophila melanogaster* than for euchromatin. Such problems are more difficult to investigate in plants. Nevertheless, recent investigations of Camara, Wagner and Gardé[3] on autosomes in *Triticum* indicate the existence of heterochromatic zones of higher susceptibility to X-rays.

The present communication is confined to *Cannabis sativa*, the heterochromosome *X* of which has a definite form and a greater amount of heterochromatin than the autosomes of *Triticum*; normally, it has two arms, one longer than the other, each containing two euchromatic zones separated by a heterochromatic zone. For this reason, *Cannabis sativa* is an adequate material for such investigations.

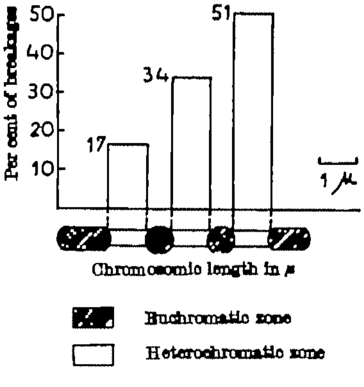
About fifty seeds are arranged on a cylindrical surface of 4 cm. diameter, at a distance of 2 cm. from a radium tube 4·4 mm. high, with a diameter of 7·8 mm. and containing 200 mgm. radium El. Seeds are irradiated for 40, 80 and 200 hr., which represents respectively about 16,800, 33,600 and 84,000 r. After-washing for half an hour, two to eight days germination and half an hour pre-fixation in a solution of 0·043 per cent oxyquinoleine (evidence of centromeres), the root tips are fixed in acetic-alcohol solution (3–1) and followed by Feulgen squashes.

We observed giant cells which present the following characters: great number of nuclei (20–50), nuclear polymorphism, variability of chromatic bodies, presence or absence of nucleolus, great amount of atypic mitosis with slightly and deeply coloured chromosomes and abnormal chromosome numbers. The plasmodia seemed to be of procambial origin. The number of mitoses was higher in irradiated plants (20–30 per cent) than in non-irradiated plants (1–2 per cent). The cytological abnormalities of heterochromosome *X* were chromosomic bridges, breakages and translocations. Breakages occur most frequently in the *X* heterochromosomes, as indicated in the accompanying table.

PERCENTAGE OF OBSERVED CELLS SHOWING ABNORMALITIES

Autosomic bridges	13·2
Heterochromatic *X* bridges	13·8
Heterochromatic *Y* bridges	7·1
Autosomic breakages	18·0
Heterochromatic *X* breakages	36·5
Heterochromatic *Y* breakages	3·0
Translocations *Y*—*X*	2·0

A distinctive property of heterochromosome *X* consists in an abnormal extraposition during mitotic metaphase, and in many cases we observed this extraposition. Translocations on the terminal euchromatic segment of *X* were also identified. The numbers of heterochromosome *Y* were too small to enable us to discuss its radio-sensitivity. Breakages appeared in different zones of *X*, and they are generally located in the heterochromatin (see graph).



Our experiments demonstrate the existence of a high sensitivity of heterochromatin *X* to γ-rays. The number of the breakages increases along this chromosome: the breakages are more frequent for the neighbourhood of the centromere than for the heterochromatic zone of the longer arm and more frequent also for the heterochromatic zone of the shorter arm than for the centromere. It is possible that this observation could be used in order to control the sexual characters in *Cannabis*.

We wish to thank Profs. A. Monoyer and G. Gueben for much assistance.

Combined Hormone-Fungicide Sprays for Control of *Botrytis* Fruit-Rot in Glasshouse Tomatoes

In recent years, losses in glasshouse tomato crops caused by *Botrytis cinerea* Pers. have become serious in New Zealand. This is particularly true of crops treated with fruit-setting hormones, where the dead petals are retained at the calyx end as the fruit expands. These dried petals provide entry points for infection of the fruits. Heavily sporulating centres of infection thus develop early in the life of the crops, increasing the likelihood of later epiphytotic development of all phases of the disease. This is a frequent occurrence in crops treated with hormones. Some form of protection for these petals is desirable, therefore, to reduce loss of fruit and prevent early build-up of infection.

In the process of fruit-set, different parts of the corolla of the tomato flower are for a period shielded from spray—at first, part of the under petal-surface by the calyx, and later, after wilting occurs, the inner petal-surface. Because a normal fungicidal programme is not related to truss development, it does not provide efficient cover for all petal surfaces. To give the necessary protection, sprays must be applied both before and after fruit-set. The correct time for the earlier of these protective sprays coincides approximately with that for the normal fruit-setting hormone spray, and it seemed likely that a combined hormone-fungicide spray at this stage could be used.

Experiments at this Station have shown that a high degree of protection is obtained by applying a suitable therapeutant with the hormone as a truss spray at full bloom, followed by a further spray of therapeutant alone 10–14 days later. A fungicide for this purpose must be compatible with the hormone and not affect fruit development. Various therapeutants have been submitted to laboratory screening tests and to small-scale and commercial glasshouse trials. In the laboratory screening tests, materials were applied at various rates with β-naphthoxyacetic acid at 50 p.p.m. to dry sterile tomato petals affixed to suitable holders for inoculations and incubation. The small-scale glasshouse trials involved inoculation, in humidity cabinets, of developing fruits with attached petals. Of the materials tested, copper fungicides were notably ineffective; but several other therapeutants proved effective, though usually at 1½–3 times the strengths recommended for other diseases. Included among those tested were certain organo-mercurials, thiocarbamates, tetramethyl thiuram-disulphide, 2,3 dichloro 1,4 naphthoquinone, 8-hydroxyquinoline sulphate and 8-hydroxyquinoline benzoate. Compatibility tests of promising materials were made on emasculated trusses of potted tomatoes. Only four of these materials at the effective concentration proved to be compatible with the hormone and did not damage the trusses. These were 'Fermspray' (ferric dimethyl dithiocarbamate), 'Zirospray' (zinc dimethyl dithiocarbamate), 'Phygon XL' (2,3 dichloro 1,4 naphthoquinone), and 'Thirospray' (tetramethyl thiuram disulphide).

Commercial glasshouse trials of selected materials were made on spring crops in which the first three trusses were treated as outlined above. In two of these trials heavy natural infection developed, and results showed the method—that is, application of a combined hormone-fungicide spray—to be successful. In one of these trials the use of 'Fermspray' (0·5 per cent) and 'Phygon XL' (0·15 per cent) reduced *Botrytis* fruit-rot by 73 per cent and 53 per cent respectively on the treated trusses. Neither of the treatments adversely affected yield or quality of fruit. Spray residues on mature fruit were negligible. A measure of the severity of infection in the house can be judged by the fact that an average of almost seven fruits per plant (approximately 25 per cent) were lost from the three treated trusses in the check plots.

Apart from effecting a considerable saving of fruit at small cost, use of this new combined hormone-fungicide technique greatly delays build-up of infection, thus reducing the chance of later epiphytotic development of *Botrytis*. Trials are proceeding with the above and other materials. Detailed results will be published elsewhere.

Bact. coli as a Food Supplement

The idea of using micro-organisms as food supplements is now commonplace, and a great deal is known about the use of yeast and *Chlorella*. Experimental work carried out recently at these laboratories suggests that equal, if not greater, possibilities exist in the use of *Bact. coli* cultures. These researches have been concerned solely with the effect of the addition of *Bact. coli* to basal diets, and no attempt has been made yet to ascertain the biochemical background of the results.

The material used consisted of heat-killed whole organisms, without removal of endotoxin. The strain was one selected at random from a collection of calf scour strains. The culture medium was a simple synthetic one, with ammonia as a nitrogen source and glucose as a carbon source. The aeration technique employed has been described[1]. Batches of 100 litres of this culture yielded about 400 gm. of bacterial protein, calculated as N × 6·25.

Uniform groups of young rats were fed *ad lib.* on a basal diet containing 11·5 per cent of protein and consisting of barley meal 2 parts, bran 1 part and 0·5 per cent cod liver oil. The effects of supplementing this diet with fishmeal and bacterial protein were observed by weekly weighings over periods of 3 or 4 weeks. It was shown by repeated experiments that 5 per cent of *Bact. coli* protein and 5 per cent of fishmeal protein produced equal and significant increases in weight gains. The optimum quantity of bacterial protein has not been determined, but it appears to lie between 2 and 5 per cent. Feeding of bacterial protein at a level of 1 per cent induced regular but retarded growth. Nevertheless a group consisting of five male and five female rats fed through life on this level bred normally, and four of the females reared normal litters.

It appeared probable from these experiments that *Bact. coli* protein could serve as a substitute for animal protein. Some indication was obtained, however, that when the bacterial protein diet was fed to very young rats, an improved growth-rate resulted if 1 per cent of fish solubles was added. ($P = 0 \cdot 1$, with groups of eight rats.)

The results of experiments on chicks suggest that there may be a fortunate combination of essential dietary factors in *Bact. coli* protein and fish solubles. When a basal diet containing 11·9 per cent of protein and consisting of barley meal, bran, 2 per cent grass meal and 0·5 per cent cod liver oil was supplemented with either one of these, grossly subnormal growth-rates were observed; but when both were added, the bacterial protein at 5 per cent and fish solubles at 1 per cent, the chicks grew from day-old to four weeks old at a rate significantly greater than control groups with fishmeal and fish solubles, and at the same rate as control groups fed on a well-known brand of chick mash. A group of 12 Rhode Island Red × Light Sussex cockerels was reared entirely on this diet and weighed an average of 5·0 lb. at 14 weeks, with one cockerel weighing 6 lb. The optimum percentage of bacterial protein for chicks has not been determined; but it is thought to be substantially less than the 5 per cent used in these experiments. It is known to be greater than 1 per cent.

It would appear, therefore, that cereals can be made into a chick-rearing ration by the addition of *Bact. coli*, fish solubles, cod liver oil, and grass meal. The economic advantages of such a diet in Britain are outstanding; the cod liver oil involves no change from current practice, and the grass meal and fish solubles are abundantly available in relation to the small amounts needed. Further, the fact that the peculiarly exacting demands of the chick can be met warrants the prophecy that diets based on *Bact. coli* protein for other farm animals could be evolved with little difficulty.

Inter-relations between Filarial and Malarial Infections in *Anopheles gambiæ*

THE dual role of *Anopheles gambiæ* as a vector of both human malaria and bancroftian filariasis in Africa has long been established. Recently a curious relation between the two infections in the mosquito has come to light, for which there is no really satisfactory explanation.

In the course of routine dissections of wild-caught *Anopheles gambiæ* in Dar-es-Salaam, Tanganyika, during 1947–48, it was noted that while *A. gambiæ* had a high rate of infection with malaria parasites and with filaria larvæ, it was very rarely that one and the same mosquito was infected with sporozoites and mature filaria larvæ (Table 1), all mosquitoes being dissected one or two days after capture.

Table 1. RECORD OF MIXED INFECTIONS OF *A. gambiæ* WITH SPOROZOITES AND MATURE THORACIC FILARIA LARVÆ. (DAR-ES-SALAAM, 1947–48)

Total *A. gambiæ* dissected	Gland infections	Mature thoracic filaria larvae	Mixed infection
426	41	14	1

In this series of dissections mature thoracic filaria larvæ alone were considered, that is, those active larvæ which appear during routine extraction of the salivary glands; this stage is reached 9–10 days after the infective feed, and immediately precedes head infection in the mosquito. No dissections for head and proboscis filarial infections were made.

As the sporozoites appear in the salivary glands of the mosquito about ten days after the infective feed, and as the filaria larvæ take about the same period to reach the mature thoracic form, mosquitoes infected with either parasite have one important feature in common, namely, that they are at least ten days old, and probably older.

During 1952 further and more detailed observations were made in localities near Accra, Gold Coast, mosquitoes being examined not only for mature thoracic forms but also for the more advanced head and proboscis forms. The dissection record is shown in Table 2, most mosquitoes being dissected on the day after capture.

Table 2. RECORD OF MALARIA AND FILARIA INFECTIONS IN *A. gambiæ* (GOLD COAST, 1952)

Gland infections	
Number dissected	492
Number positive	15
Sporozoite-rate	3·1%
Filarial infections	
Number dissected	704
Number with all forms mature larvæ	28 (4·1%)
Number with head or proboscis larvæ only	9

Of forty-three wild-caught *A. gambiæ* positive for either sporozoites (15) or mature filaria larvæ (28), only two were found infected with both parasites.

Dissections for double infections with oocysts and mature filaria larvæ also revealed the rarity of mixed advanced infections (Table 3).

Table 3. RECORD OF MIXED INFECTIONS OF *A. gambiæ* WITH MATURE OOCYSTS AND MATURE FILARIA LARVÆ (GOLD COAST, 1952)

Total *A. gambiæ* dissected for oocysts and mature filaria larvæ	490
Number with oocyst infections	28
Number with mature filaria larvæ	8
Number with mixed infections	0

It is not unusual to find *A. gambiæ* with sporozoites or mature oocysts also harbouring immature, stumpy, thoracic forms of filaria larvæ; but the scarcity of mixed advanced infections in mosquitoes which have this important age factor in common is difficult to understand.

In interpreting these findings in wild-caught mosquitoes, one has always to bear in mind the possibility that some of the filarial infections may not necessarily be of human origin—that is, *Wuchereria bancrofti*—a point long appreciated, and recently emphasized by Raghavan *et al.*[1]. In the present series of experiments it appears likely that the great majority of these filarial infections really are of human origin in view of *A. gambiæ*'s well-known association with man, and that the human population in both areas had a fairly high infection-rate with *W. bancrofti*.

One possible explanation of these findings has been tested, namely, the suggestion that the parallel development of filaria larvæ and malaria parasites cannot normally proceed to maturity in the same mosquito. An unusual opportunity for testing this was provided by a five-year old African child who was a chronic infector with both *falciparum* malaria and *W. bancrofti*. On two occasions batches of laboratory-bred *Anopheles gambiæ* were fed on him at night between 9 and 10 p.m. Out of 49 *gambiæ* surviving for dissection from ten days onward, 15 were found infected with malaria or filaria; of that number 2 showed mixed infections of mature thoracic larvæ and mature oocysts, and one was infected with both sporozoites and mature filaria larvæ in thorax and head.

Although these mixed advanced infections appear to be so scarce in Nature, these experiments show that both infections can actually proceed side by side and that there is no physiological barrier to prevent one and the same anopheline picking up both infections from the human host, and in turn becoming infective with both parasites.

In trying to interpret these figures it must be remembered that when the malarial infection has reached the sporozoite stage in the salivary glands of the mosquito, the infection may persist there for many days or even weeks. With the filarial infection, however, the infective stages in the head and proboscis are fairly transitory, and within about fifteen days of the infective feed they may have left the mosquito without leaving any trace behind. When we find a mosquito with a sporozoite infection we know that it must be at least ten days old; but it may, of course, be a much older mosquito which has also acquired, developed and finally lost a filarial infection.

These observations form part of a much wider investigation into the relative importance of each human age group in the African village community as a source of malarial and filarial infection. It is hoped that the outcome of this work may provide a satisfactory explanation of this curious mutual exclusion of advanced malarial and filarial infections in *Anopheles gambiæ*.

Pseudotuberculosis among Stock-Doves in Hampshire

DURING December 1952, many stock-doves were found lying dead under the trees where they normally roost in the Damerham–Martin district of Hampshire. They appeared to be in good condition, but post-mortem examination of forty-two of them showed that death was due to a virulent strain of *Pasteurella pseudotuberculosis*. There were small caseating nodules in the liver and spleen, both of which organs were slightly enlarged. The outbreak continued throughout December and January, but began to decrease in February.

In order to find what other species were carrying the infection, all birds and rodents found dead in the district were examined, and many others were shot for examination. These included seventeen wood pigeons, one lark, one redwing, twenty-seven jackdaws, seven rooks, three jays, one sparrow, nine rabbits, six hares and fifty-two grey squirrels, and the bacterium was recovered from the lark, one wood pigeon, one jackdaw, one rook and one hare. The lark had been picked up dead, and the liver showed a close network of caseating fibres which traversed the whole organ, while the spleen contained two outstanding nodules about the size of a pin-head. Bacteria were recovered from both organs. The other infections were found in shot animals and were cryptic, for no signs of disease were noted in any organ. An attempt to infect bantam chicks gave negative results.

Many bodies are sent to this laboratory for examination, and during this period the bacterium was recovered from a rabbit in Hertfordshire and from two pigeons from Norfolk.

This infection has been repeatedly reported from rodents and sporadically from birds, though more serious outbreaks have been described from turkeys[1], fowls and pheasants[2] and from ducklings[3]. We ourselves have isolated the bacterium from grey partridge, pheasant and bob white quail, the latter being a bird reared in captivity. On this occasion, however, there seemed to be little disease among rodents, and it is particularly interesting that the wood pigeons were not seriously affected, in spite of their close affinity to stock-doves. Though the number of wild birds examined was small, there is evidence that several distinct species may be reservoirs of infection.

Storage of Unfertilized Rabbit Ova: Subsequent Fertilization and the Probability of Normal Development

PREVIOUS investigations[1–4] have shown that fertilized rabbit ova stored at 10° C. or at 0° C. for various lengths of time can develop into normal young when transferred into recipient rabbits. A recent experiment[4] has further demonstrated that freshly ovulated unfertilized ova can be kept at 10° C. or at 0° C. for 48–72 hr. without all losing their fertilizability when transferred into the Fallopian tubes of rabbits which had been bred twelve hours before. This communication reports the subsequent fertilization and the probability of normal development following the transfer of unfertilized ova which had been stored for certain lengths of time.

Unfertilized ova were obtained from the Fallopian tubes of superovulated albino rabbits. The ova were recovered 11–13 hr. after the hormone injection which induced ovulation. They were suspended in a mixture of equal parts of buffered Ringer solution and rabbit serum and were stored in small 'Pyrex' tubes, either at 10° C. in a water-bath, or in ice at 0° C. after an initial 1-hr. acclimatization[1] at 10° C. Fertilizability of the ova was then tested (*in vivo*) after 6–7 and 30–31 hr. at either temperature.

Recipient does were non-albino (black-eyed). About half of them were artificially inseminated with sperm from albino bucks. Six to seven hours later ova were transferred and 25 mgm. of macrocrystalline progesterone was injected subcutaneously. This progesterone treatment was repeated eight days later. The other recipient does were mated with an albino buck, and also injected with ovulation-inducing hormone, 6–7 hr. before ova were transferred. In order to eliminate the ova of these recipient does, the large ovarian follicles were punctured at the time of ovum transfer and the fluid content of the follicles was evacuated by means of a capillary suction pipette. Ova stored at 10° C. were transferred to the left tube, and those kept at 0° C. to the right tube, of the same recipient doe.

Most of the does were killed, or examined at laparotomy, 20–26 days after ovum transfer. Their ovaries and uterine contents were examined, and the numbers of normal fœtuses and of degenerate embryos or placentæ were recorded. The result of the experiments is presented in the accompanying table.

STORAGE OF UNFERTILIZED RABBIT OVA AND SUBSEQUENT FERTILIZATION AND DEVELOPMENT

Storage temperature (°C.)	Storage time (hr.)	No. of recipients		No. of ova transferred	Normal development as percentage of ova transferred	Degeneration after implantation as percentage of ova transferred
		Total	Pregnant			
0°	6–7	9	5	73	11	7
	30–31	8	3	57	7	0
10°	6–7	10	6	69	3	4
	30–31	8	3	58	4	2
Control (No storage)		4	2	30	27	0

The probability of normal development is much smaller when the ova are stored before fertilization instead of afterwards (3–11 per cent survival when stored 6–31 hr., against 11–37 per cent after 24 hr. storage of fertilized ova[5]). Survival of fertilized ova was better at 10° C. than at 0° C.[5] (37 per cent as against 11 per cent after 24-hr. storage); but the present results show no statistically significant difference between the effects of storage at 10° C. and at 0° C.

The method employed in the present study is not the most efficient for the determination of fertilization and normal development, because the reproductive state of the recipient animal was not optimal, and thus a high proportion of recipients did not become pregnant. In those recipients of which the large follicles were broken, the corpora lutea were not fully developed and some of the broken follicles had failed to develop into corpora lutea when examined at autopsy. Thus the implantation and the development of embryos may have been hindered. In those recipients which were treated with progesterone, a method previously reported as successful in maintaining the development of transferred fertilized ova[3], the transportation of the spermatozoa and of the transferred ova, and the process of fertilization, may be disturbed.

Moreover, in the determination of the fertilizability of ova[4], it was reported that spermatozoa were often observed in the zona pellucida or in the perivitalline space and yet the ova were not fertilized. Since the nuclear configuration and the chromosome number of ova parthenogenetically activated following low temperature storage was very similar to that of a normal fertilized ovum[6] it seems that parthenogenetically developed ova with sperm in the zona pellucida might have been mistaken as fertilized in the previous report[4]. The difficulty of determining whether the stored ova were fertilized or parthenogenetically developed *in vivo* was further experienced under present experimental condition, when the ova were examined after transfer for one day. Although the possibility exists that many actually fertilized ova failed to develop, the proportion of ova which appeared to be fertilized (nucleated cells with sperm in zona pellucida) corresponds in no way with the proportion that underwent normal development. Thus two interpretations exist: (1) that previous estimations of the percentage of actually fertilized ova were too high; or (2) that cold storage of unfertilized ova has adverse effects on the physiological process leading to future development after fertilization.

Taking all these possibilities into consideration, the low percentage of development as reported here in the transfer of unfertilized ova would be expected.

This work was supported by grants from the Rockefeller Foundation and the Dickinson Memorial Fund of the Planned Parenthood Federation. Sincere thanks are due to Mr. Robert F. Slechta for assistance, and to Dr. G. Pincus for constant interest during this investigation.

Respiratory and Digestive Anatomy of a Microhylid Tadpole, *Hypopachus aguæ* Stuart

THROUGH the courtesy of Mr. L. C. Stuart, some specimens of tadpoles of the microhylid frog *Hypopachus aguæ* Stuart, from Guatemala, have been made available for dissection. The internal anatomy of tadpoles of this family is almost unknown, apart from some aberrant species[1] and a brief account of some others[2].

Features of special interest are as follows. (1) An œsophagus divided into two lateral halves by a partial septum arising from the dorsal wall and extending almost to the ventral wall; each half receives one of the two mucous feeding-cords which are formed in the posterior parts of the pharynx. (2) The presence of a 'manicotto' (so-called larval stomach), previously only known in *Rana*. (3) Reduced gills, with filaments only on the second and third arches; the reduction has, however, not proceeded to the extremes found in *Glyphoglossus* and *Calluella*, nor are the gill filters so large as in those species; the filaments are arborescent, as in other microhylids, and not as in *Rana* or *Bufo*.

The animals are clearly highly specialized for microphagy, since the œsophagus, already small in comparison with that of *Rana* or *Bufo*, has its lumen still further reduced by the thick septum, so that only narrow mucous cords can enter. They appear well adapted for life in a normal pond, having neither the huge filters (with rudimentary gills) needed for life in oligotrophic waters, nor the well-developed gills (with small filters) needed for life in a puddle. They were found in such a pond.

Hæmolytic Disease of New-born Pigs caused by Iso-Immunization of Pregnancy

HÆMOLYTIC disease of the new-born is now well recognized in the human subject and is known to be due to iso-immunization of the mother by fœtal red cell antigens of the *Rh* group. Within the past few years the condition has been observed in foals[1,2]; but so far as we are aware, its existence as a naturally occurring disease has not yet been established in any other species, although the possibility of a comparable pathogenesis in other animals has been suggested.

The classic pattern of hæmolytic disease consists in the mating of serologically incompatible parents. As a result the fœtus inherits antigen from the father which is passed to the mother and against which she produces antibody. This antibody, which has power to destroy the red blood cells of the young animal, may, in favourable circumstances, pass back into the fœtus or it may become concentrated in the mother's milk. The clinical condition of icterus gravis neonatorum has long been appreciated in human as well as in veterinary medicine; but more recently it has come to be recognized as a common symptom of hæmolytic disease.

Recently, we have carried out investigations which establish the existence of hæmolytic disease in pigs, following serious losses among baby pigs within the first week of life on one large farm in the Midlands[3]. In a high proportion of cases there were no survivors from affected litters; although all piglets appeared to be healthy at birth, varying degrees of clinical jaundice became evident at about the forty-eighth hour, and it was usual for the entire litter to be dead by the fifth day. At autopsy, icterus of the skin, musculature and viscera were constant lesions, and it was common also to find congestion and enlargement of spleens, some of which were nearly black in colour. Perhaps the most striking feature at post-mortem examination, however, was provided by the quantity of blood-stained peritoneal fluid which was present in nearly all carcases, and this, together with the darkened urine, served to indicate the speed at which red blood cells were being broken down by maternal iso-antibody. In general, post-mortem findings provided evidence of acute disease and depicted rapidly progressing hæmolysis.

With the generous assistance of Dr. R. R. A. Coombs, of the Department of Pathology, Cambridge, it was possible to apply the serological techniques of *Rhesus* factor work to the diagnosis of the disease in pigs and to demonstrate the existence of iso-immunization. Citrated blood samples from affected piglets were subjected to the direct antiglobulin sensitization test (Coombs test), using anti-pig globulin serum prepared in rabbits. Rapid and complete agglutination was obtained of all samples. Parental blood incompatibility was shown also by well-marked reaction between serum from affected sows and the red cells of the boar.

Although in hæmolytic disease of the human infant due to iso-immunization, icterus gravis neonatorum is common, it is by no means constant, and the condition may provoke a wide variety of symptoms. Very little knowledge exists yet concerning the manifestations of the disease in animals; but it seems reasonable to assume that they may be as varied as those of man and that some well-known clinical entities, the cause of which is still obscure, may be shown to be associated with maternal iso-immunization. Much work needs to be carried out into this kind of disease in animals, for with the necessary information relating to blood groups of the various species might emerge knowledge which could lead to the avoidance of losses resulting from the mating of serologically incompatible parents.

Note added in proof. Since this article was written we have learned of the work of Szent and Szobó into hæmolytic jaundice of new-born pigs in Hungary[4].

Paper Chromatography of Keto-Acids

BLOOD pyruvic acid estimations were being made in this laboratory, and it was important to test the specificity of the method employed. The acid was extracted as the hydrazone by the method of Friedemann and Haugen[1] (using toluene for the extraction) and the hydrazones chromatographed under the conditions which Altmann *et al.*[2] had found successful.

Human blood was deproteinized with 10 per cent metaphosphoric acid and analysed for pyruvic acid[1]; the final ice-cold sodium carbonate solutions of the phenylhydrazones were acidified with concentrated hydrochloric acid and extracted into ether, which was removed under reduced pressure.

The hydrazones from blood were run with the hydrazones of pyruvic acid, phenyl-pyruvic acid, α-ketoglutaric acid, acetoacetic acid and acetone, which were prepared by incubating the keto-compound with a 0·1 per cent solution of 2 : 4-dinitrophenylhydrazine in 2 *N* hydrochloric acid. The precipitated hydrazones were centrifuged, and the precipitates washed twice with 2 *N* hydrochloric acid and twice with water.

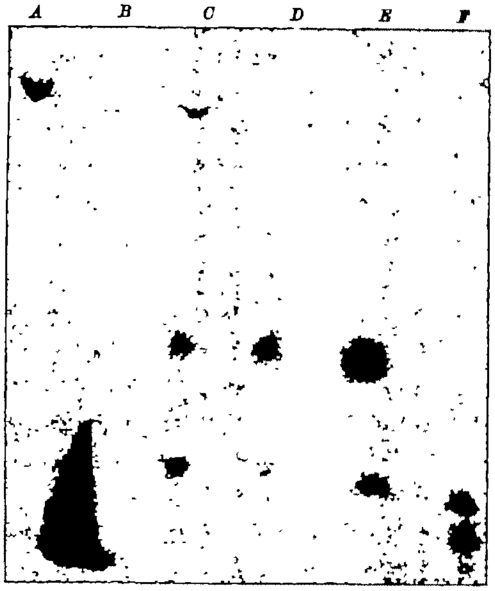
The chromatograms were photographed through a Wratten tricolour blue filter. The accompanying photograph illustrates the main findings. The average

R_F values for the hydrazones of some keto compounds from runs carried out at room temperature were :

α-Ketoglutaric acid	0·12
Pyruvic acid	0·58
Acetoacetic acid	0·60
Phenylpyruvic acid	0·84
Acetone	1·00

The hydrazones of blood were run on ten separate occasions, four spots always being observed. Two of these spots were accounted for by the hydrazone of pyruvate; but there were also two smaller, faster-running spots, which were barely visible until photographed. These latter were identified as the hydrazone of phenylpyruvate. The hydrazone of pure pyruvate gave two clear spots on all occasions. Yet when pure pyruvic acid was added to metaphosphoric acid and treated as for blood, the larger, slower-moving of the two spots often appeared to be divided into two. Partition chromatography of blood also frequently showed the same sub-division of the larger pyruvate spot. Since a blank of metaphosphoric acid also showed a spot at this level, this phenomenon is perhaps due to some 2 : 4-dinitrophenylhydrazine coming through the extraction process. It was also observed that acetoacetate hydrazone undergoes some decarboxylation to acetone during chromatography.

Cavallini, Frontali and Toschi[3,4] had previously carried out similar experiments, using a butanol–ethanol 20 per cent mixture as the mobile phase. They collected blood by the method of Long[5] and analysed it for pyruvic acid by Bueding and Wortis's modification[6] of Lu's[7] method. They found[4] that blood had two spots which they identified as α-ketoglutaric acid and pyruvic acid, and two unidentified spots, one with R_F 0·53, and another, which appeared occasionally, behind the solvent lines. They concluded that only about a third of the amount of keto-acid could be accounted for by pyruvate, the remainder being due to α-ketoglutaric acid and two unidentified compounds.



(A) Hydrazone of α-ketoglutaric acid. (B) Hydrazone of acetone (excess hydrazone was applied to the paper on this occasion; the spot usually lies on the solvent line). (C) Hydrazones from blood analysed for pyruvic acid as Cavallini *et al.* had done (ref. 4). (D) Hydrazones from blood analysed for pyruvic acid according to Friedemann and Haugen (ref. 1). (E) Hydrazone of pyruvic acid. (F) Hydrazone of phenylpyruvate

The specificity of the methods of extraction of Friedemann and Haugen[1] and of Cavallini *et al.*[4] were compared, using the solvents advised by Altmann *et al.* for chromatography (see photograph). Blood analysed as described by the latter showed one spot corresponding to α-ketoglutaric acid, two to pyruvic acid, two to phenylpyruvate, and a suspicion of two other spots, having R_F values 0·44 and 0·73. Blood analysed according to the former's method again showed only four spots, corresponding to pyruvate and phenylpyruvate hydrazones.

It would appear, therefore, that the method of Friedemann and Haugen allows separation of pyruvate together with some phenylpyruvate from the other keto-acids in blood in a way more specific than the method used by Cavallini *et al.* It is doubtful whether the paper chromatography of keto-acids can be made quantitative until the origin of the two spots for both pyruvate and phenylpyruvate is explained.

I wish to thank Prof. Charles Wells for his continued encouragement; Dr. S. P. Datta, of University College, London, for a gift of phenylpyruvate hydrazone; and Mr. Wilfred Lee, of the Central Photographic Department, University of Liverpool, for his co-operation in photographing the chromatograms. I also wish to acknowledge a grant from the Medical Research Council.

A Chromatographic Colour Reagent for a Group of Amino-Acids

THE condensation of aromatic aldehydes with amino-acids to give coloured derivatives has had limited use in paper chromatography. Ehrlich's reagent, *p*-dimethyl-amino-benzaldehyde, has been used as a reagent for tryptophane and indole[1] and for citrulline[2]. *o*-Phthalaldehyde has been used as a reagent for glycine, histidine and tryptophane[3]. Earlier workers have used other aldehydes, including vanillin, in strongly acid solution as reagents for tryptophane[4].

We find vanillin followed by alcoholic potash to be a chromatographic reagent of considerable specificity. One-way chromatograms are run on 20-cm. sheets in a Dent–Datta frame[5]. They are then dried and dipped in a freshly prepared 2 per cent solution of A.R. vanillin in *n*-propanol and heated at 110° for 10 min. Faint yellow colours are shown by many amino-acids at this stage. Ornithine gives a strong and lysine a weak green-yellow fluorescence in the ultra-violet.

The chromatograms are then dipped in 1 per cent alcoholic potash and heated again at 110° for 10 min. Ornithine gives a salmon spot about 30 sec. after commencing heating; the spot quickly fades to yellow-brown on further heating. This is specific for ornithine, none of the other compounds tested giving it. Proline, hydroxy-proline, α-, β- and γ-pipecolinic acid, baikiain (Δ^4-tetrahydropyridine-2-carboxylic acid) and sarcosine show up as red spots after about six hours standing at room temperature and reach maximum intensity after standing overnight. β- and γ-pipecolinic acids give comparatively faint colours.

The complete range of commercially obtainable α-amino-acids gave either no colour or indefinite faint browns, with the exception of glycine, which gave a quite strong greenish-brown. This colour, however, is not easily distinguishable from the faint browns given by many amino-acids, and hence vanillin is not recommended as a glycine reagent. β-Alanine, β-amino-*iso*-butyric acid, γ-amino-*iso*-butyric acid, glutathione, betaine, hippuric acid, creatinine, glycocyamine, ethanolamine, pyrrole, pyrrolidine, pyrrolidone and indole also gave negative results. In general, the red spots only fade slightly in a week, though they tend to be obscured by darkening of the background in two or three days. Baikiain is an exception, becoming brown in about 20 hr. The background darkening is rapid after running the chromatograms in phenol, the spots also becoming discoloured. Results are satisfactory after running in butanol–acetic acid, collidine–lutidine or the acetone–urea–water solvent of Whitehead and Bentley[6]. The accompanying table shows the minimum detectable quantities of the substances giving well-defined colours in daylight when run on 15-cm. one-way acetone–urea–water chromatograms.

SENSITIVITIES OF AMINO-ACIDS TO VANILLIN

	µgm.		µgm.
Ornithine (30 sec.)	0·5	α-Pipecolinic acid (16 hr.)	1
Sarcosine (16 hr.)	0·5	Baikiain (16 hr.)	1
Proline (16 hr.)	1	β-Pipecolinic acid (16 hr.)	4
Hydroxyproline (16 hr)	1	γ-Pipecolinic acid (16 hr.)	5

The use of a range of aldehydes and ketones as specific amino-acid chromatographic colour reagents is being investigated and will be described later.

We thank Dr. T. F. Dixon for helpful criticism and Dr. C. E. Dent and Mr. I. I. Smith for samples of various amino-acids.

Detection of 5-Hydroxytryptamine by Paper Chromatography

IT is well known that enterochromaffin cells acquire a golden-yellow fluorescence after fixation in formaldehyde, due probably to their content of enteramine (5-hydroxytryptamine). We have now carried out chromatographic experiments with synthetic 5-hydroxytryptamine creatinine phosphate to study the sensitivity and specificity of this reaction. We used a butanol – acetic acid – water solvent and a developer composed of nine parts of a solution of potassium dichromate (0·1 per cent) and one part of formaldehyde solution (37–41 per cent). After spraying and heating at 100–110° C. for five minutes, the paper is viewed under ultra-violet light. Under these conditions, 5-hydroxytryptamine (R_F value 0·38) produces a golden-yellow fluorescence immediately after the heating and this persists for days; quantities as small as 0·2 µgm. base can be detected. The behaviour of bufotenine and bufotenidine is quite similar to that of 5-hydroxytryptamine. Tryptamine gives a bright yellow fluorescence if more than 2·5 µgm. are present; but this develops slowly. Tryptophane likewise gives a yellowish fluorescence if 2·5 µgm. are present, while 5-methoxytryptamine gives a yellow-orange fluorescence if similar amounts are present. Bufothionine, histamine, histidine, tyramine, tyrosine and *p*-norsynephrine produce no fluorescence, while that with adrenaline and noradrenaline is very feeble. *m*-Norsynephrine has already been shown to produce a violet fluorescence under these conditions if 0·5 µgm. is present[1]. Such a small amount of 5-hydroxytryptamine (0·2 µgm.) can also be detected with alkaline Folin reagent (producing a blue colour), Pauly reagent (red), diazotized *p*-nitraniline reagent (red-brown), N.N.C.D. reagent of Heinrich and Schuler (red-brown), Gibbs reagent (brownish-violet) and Ehrlich's reagent (blue)[2].

The fluorescent reaction may therefore be of value in tracing small quantities of 5-hydroxytryptamine in tissue extracts. The diazotized *p*-nitraniline reagent may also assist, since hydroxyindolealkylamines (for example, 5-hydroxytryptamine, bufotenine and bufotenidine) give an orange-brown colour whereas the indolealkylamines (for example, tryptamine) usually give a faint yellowish colour in higher concentrations.

Quantitative Paper Chromatography of Traces of Metal with the Aid of Radioactive Hydrogen Sulphide

THE methods so far known for the determination of traces of metal are often expensive and take much time. Moreover, either the sensitivity is low or the error is large. On the other hand, quantitative paper chromatography has not developed far enough yet to give a competitive solution. I have investigated the possibility of using radioactive hydrogen sulphide ($H_2{}^{35}S$).

The quantitative reaction with radioactive hydrogen sulphide and the oxidation of the sulphides formed a first difficulty. This was solved in the following way. After chromatography, the dried papers are conditioned over ammonia for half an hour. They are then put into a glass bell-jar which also contains some ammonia, some hydrazine and some radioactive zinc sulphide ($Zn^{35}S$). The jar is connected with a source of pure nitrogen and with the vacuum-line (both through gas-locks). After washing out the jar with nitrogen three or four times, vacuum is once more established. During this time a plastic shell is put over the jar and nitrogen is conducted through this shell. After adding some water and concentrated sulphuric acid to the zinc sulphide, the whole apparatus is put in the dark. After 10 min. the hydrogen sulphide is fixed by passing it through zinc acetate.

It appeared that 2 c.c. concentrated ammonia, 0·2 c.c. hydrazine hydrate, 3 mgm. radioactive zinc sulphide, 0·2 c.c. water and 0·2 c.c. acid are sufficient for the reaction of 100 μgm. of metal. The influence of the shape of the spot and the thickness of the paper were small.

It was necessary to wash the paper to remove metals retained in it. Successive washings with 0·1 *N* hydrochloric acid, water, 1 per cent sodium citrate and water removed most of the metals. For the determination of quantities of metal less than 1 μgm., this washing needs improving.

When applied to biological material, the method prohibits the use of sulphuric acid for breaking down the specimen, as this yields too high salt concentrations. For very small samples dry-ashing at 400° C. was sufficient; for samples of about 1 gm. the carbon residue had to be treated with ammonium nitrate and hydrogen peroxide; the residue was then taken up in hydrochloric acid.

For very small quantities of metal (cobalt), in order that a much greater proportion of the hydrochloric acid solution than usual could be transferred to the paper, we used a strip of paper (3 cm. × 12 cm.) folded like an accordion for absorption of the solution, and placed this pleated paper in the fold of a chromatographic paper between two glass rods. This is a variant of von Euler's[1] method.

All chromatography was performed by the ascending method, using jam-pots with paper cylinders held together by paper cuffs, for the quick selection of the correct solvents. For analysis larger cylinders were used, each placed in a Petri dish, and the dishes in a big glass tray. For the pleated papers broad sheets of paper were used, kept in the perpendicular position by sticking a glass pin through the upper part. It was found preferable to use the one-dimensional method, transferring each time new amounts of the same solution to a new paper, using different solvents for different groups of ions to be separated.

In view of the action of the ions potassium, sodium, calcium, phosphate and others always present in larger quantities in biological material, and also in view of the fact that non-evaporating complexes are not suitable, only the following solvents have been successful so far (all proportions being v/v):

Butanol-saturated with *N* HCl. for Mo—Zn and others.
Acetone (75 parts), 4 *N* HCl (25 parts): for Mn—Cu—Fe—Zn
Pyridine (60 parts), H_2O (40 parts), followed by acetone (75 parts), 4 *N* HCl (25 parts), 1 $^0/_{00}$ KI: for Co ('accordion').

For thallium, mercury and tin several solvents already described in the literature were successful, and also:

Butanol (90 parts) with ethylaceto acetate (10 parts) saturated with 0·1 *N* HNO_3: for Hg, Sn, Tl; nitrates 'accordion'.
α-Picoline (60 parts), H_2O (40 parts). for Tl and Hg; 'accordion'.
Butanol (80 parts) with *tert.* butanol (20 parts) saturated with H_2O: for Tl; nitrates 'accordion'.

Further new suitable solvents were:

Pyridine (60 parts) 0·1 *N* HCl (40 parts); followed by pyridine (60 parts), H_2O (40 parts): for Mn.
CCl_4 (80 parts) with acetylacetone (20 parts) saturated with 1 *N* NH_4OH: for Cu.
α-Picoline (60 parts), 0·2 *N* NH_4OH (40 parts), 1 per cent diethylamine: for Mo.

The advantages of the method are: once the biological material is broken down, any metal can be detected and no concentration with oxine or suchlike is needed; the sensitivity is very great (comparable with spectrography); the method is not costly and can be carried out on a large scale and partly automatically.

A detailed description will be published elsewhere. I thank Mrs. C. J. H. Stutterheim-Kanis and Mrs. A. C. M. Peer-Borst for practical assistance.

Paper Chromatography of Amino-Acids in Cerebrospinal Fluid

We have been investigating the amino-acids present in the cerebrospinal fluid obtained from patients with various diseases, using paper chromatography. Successful chromatograms require that protein and electrolytes should be removed from the fluid. There have been various methods suggested for doing this. We use a method which is simple, quick and requires apparatus that is readily available. It is based on the work of Boulanger and Biserte[1], who showed that, when biological fluids containing amino-acids are passed through cation-exchange resins, all the amino-acids with the exception of taurine are retained in the resin along with the cations, and that the anions pass through. The amino-acids can then be displaced from the resin with ammonia, leaving the cations on the column.

Boulanger and Biserte pass protein-free fluids through their suggested resin; but we have found as a result of Partridge's work[2] that, if a sulphonated polystyrene resin of the bead type is used, protein passes through unchanged. Thus in the one operation of passing the fluid through a suitable cation-exchange resin, proteins and anions are removed and the amino-acids retained. These may be displaced with ammonia and the resultant eluate evaporated under reduced pressure.

The method we use is as follows. The resin (Zeo-Karb 225) is activated with twice its volume of 10 w/v per cent hydrochloric acid, washed free of acid and then placed in a column approximately 15 cm. × 0·5 cm. The cerebrospinal fluid (1 ml.) is then passed through the column and 15 ml. of water used for washing it through. The amino-acids are displaced from the column with 15 ml. of *N* ammonia solution. The first 3 ml. of eluate are ignored. The next 12 ml. are evaporated under reduced pressure at 37° C. The dry residue is taken up in water and used for paper chromatography. The amino-acid arginine requires a much greater concentration of ammonia for its removal from the column.

We have shown that cerebrospinal fluids of high protein content can be passed through the column without the *p*H changes in the column altering the free amino-acid pattern of the fluid.

Combining this technique with the circular filter-paper method of paper chromatography suggested by Giri and Rao[3], we are able to obtain results within four hours of receiving the fluid in the laboratory. Actual bench-time is approximately thirty minutes.

Preliminary results show that the method is suitable for serum and urine.

An Analysis for Deuterium based on the Photoneutron Effect

INDIRECT methods of measuring the abundance of deuterium involve chemical preparation and very careful purification of the samples[1,2]. This disadvantage and possible source of error is avoided in a method based on the $^2D(\gamma,n)^1H$ reaction for photon energies greater than 2·2 MeV. The number of neutrons emitted from the sample in conjunction with a suitable γ-ray source is a measure of the amount of deuterium present, and, under constant experimental conditions, a direct comparison with deuterium standards may be made.

A convenient source of γ-rays is a preparation of sodium-24 for which an initial activity of at least 40 mC. gm.$^{-1}$ of sodium carbonate is possible. Each preparation affords a useful and economic measuring period, the deuterium photoneutron reaction cross-section is relatively large ($\sim 16 \times 10^{-28}$, cm.^{2}), and at this energy (2·76 MeV.) beryllium is the only other element emitting photoneutrons. The samples must therefore be free from beryllium and also from elements, such as lithium, boron and cadmium, with large absorption cross-sections for thermal neutrons, as the photoneutrons are most efficiently detected after being reduced to thermal energies in a water or paraffin moderator. These conditions of purity should not be difficult to realize, especially in medical and biological work for which the method is primarily intended. Since the various sources emit neutrons having similar energy distributions, they may be compared without measuring the density integral of thermal neutrons within the moderator in each case. Single measurements at a standard position in the moderator are sufficient.

To estimate the overall sensitivity of the method, some measurements have been made using very dilute deuterium samples irradiated by γ-rays from sodium-24 and a shallow, boron-lined pulse-ionization chamber as neutron detector. From these results, to be published in detail later, a suitable apparatus has been designed and is under construction. It consists of an annular, boron-lined ionization chamber, 20 cm. long by 20 cm. external diameter, surrounding a 9-cm. diameter lead cylinder at the centre of which is the photoneutron source. This comprises a 10, 20 or 30 ml. sample in an annular glass container enclosing the γ-ray preparation. The lead is to reduce both the γ-ray 'noise' level of the chamber and the number of photoneutrons from the deuterium naturally present in the moderator. This moderator, of paraffin wax, surrounds the chamber to a minimum depth of 20 cm. and is contained by a substantial concrete shield. With this arrangement it is estimated that a 10-ml. sample containing twice the natural abundance of deuterium in water, that is, about 0·03 vol. per cent, and a 500 mC. source of sodium-24, will yield a counting-rate—which should be a linear function of deuterium concentration and γ-ray source strength—of about 500 min.$^{-1}$ above an estimated background of about 50 min.$^{-1}$. Thus, when a reasonable quantity of the sample is available, the sensitivity of the method appears to compare well with that of other techniques, and measurements within a few per cent should be made fairly easily.

This new method will be used initially for the measurement of total body-water in the human subject. For this purpose it should not be necessary to use doses greater than 20 ml. of deuterium, instead of the order of 100 ml. commonly employed[2].

Infra-Red Dichroism in Synthetic Polypeptides

Fraser and Price[1] have recently made some interesting and fruitful suggestions concerning the origin of some of the prominent infra-red absorption bands in peptides and other substances which contain an amide group. They predict that the transition moment of the band which appears in proteins and synthetic polypeptides in the region 1,630–1,660 cm.$^{-1}$ (the C=O stretching mode with some contribution from the conjugated CN bond) should make an angle of about 20° with the C=O bond; details of the calculation are not given. They consider that this angle is sufficient to explain the low dichroism of the C=O band observed in the spectrum of poly-γ-benzyl-L-glutamate[2] (when the molecules of this polymer are assumed to be in α helices[3]).

The relation between the C=O valency bond and the transition moment of the C=O band has been examined experimentally in this laboratory, using acetanilide as a model compound. From this work it appears that the angle might be as high as 23° [4]. The transition moment is in the plane of the amide group and displaced from the C=O bond towards the direction of the line joining the N and O atoms. Bamford *et al.* point out that an angle of about 26° displacement is needed to agree with the dichroism observed in poly-γ-benzyl-L-glutamate.

Some information on dichroism of C=O and NH bands has recently been obtained from spectra of nylon 66, a material which is a better model for a polypeptide than acetanilide, in which the nitrogen atom is bonded to an aromatic ring which may affect the electron distribution of the amide group. A thin nylon specimen in which there was no complication from double orientation was obtained by grinding a thick oriented monofil of circular cross-section. The spectrum was observed with polarized radiation from a selenium transmission polarizer of high performance, and dichroic ratios 3·1 and 4·1 were obtained for the 1,640 cm.$^{-1}$ $\mathrm{C=O}$ band and the 3,310 cm.$^{-1}$ band, respectively. These results show at once that the transition moments of these bands are not parallel, although the corresponding valency bonds are expected to be nearly parallel in amide groups[3]. This effect was not observed in earlier measurements with nylon 66 owing to insufficient orientation of the specimens used. Qualitatively, the lower dichroism of the $\mathrm{C=O}$ band compared with the NH band is in agreement with Fraser and Price's suggestions, and with the observations on acetanilide; but the effect is smaller than we should expect.

If we assume (*a*) that the NH transition moment is along the valency bond, (*b*) that the $\mathrm{C=O}$ bond is normal to the chain axis[6], and (*c*) that the bond angles of the amide group are as given by Corey and Pauling[5], then the observed dichroic ratios show that the $\mathrm{C=O}$ transition moment is inclined to the valency bond in the expected sense, but at an angle of 12°, not 26° as required to explain the dichroism observed in the polypeptide spectrum. This result is obtained by assuming that nylon 66 is made of oriented crystallites and a completely unoriented fraction. It makes practically no difference to the result whether the crystallites are assumed to have perfect orientation or a dispersion of ± 10° from the fibre axis (X-ray photographs show the dispersion to be not more than ± 6°). When the result, together with the above assumptions, is used for calculating the dichroism of the $\mathrm{C=O}$ band in the poly-γ-benzyl-L-glutamate specimen used by Ambrose and Elliott, we obtained the value 6·6. The observed value is 2·6 and we are left with a major discrepancy.

Only assumption (*a*) will be discussed here. The only observations which give information on the direction of the NH transition moment appear to be those of Newman and Badger[7] on the spectrum of N-acetyl glycine. These workers concluded from measurements of dichroism that the NH bond was in the plane of the amide group, and that the αC—N—H angle was 100° ± 10°. The selected value for this angle given by Corey and Pauling is 114°. If we accept Newman and Badger's result as meaning that the NH transition moment is inclined to the bond by an angle lying between 4° and 24°, the situation is made worse, for this inclination is in a sense which brings the $\mathrm{C=O}$ and NH transition moments more nearly parallel.

The basic question raised is not so much whether the Pauling–Corey α-helix can be reconciled with the observed dichroism of a polypeptide, but whether the amide groups in nylon, in simple molecules and in folded polypeptides, can retain substantially the same parameters. If they do, then it would appear necessary to assume that, nevertheless, the angle between the valency bond and transition moment in the $\mathrm{C=O}$ group (and possibly the NH group) varies from compound to compound. This could only arise from effects of the environment. Such an effect is to be expected in bands which correspond to almost forbidden transitions, where an external force field may have a considerable effect, but the strong peptide bands are not of this kind. Changes in the hydrogen bond could produce an effect; but, in the structures assumed for the various compounds considered, such changes are supposed to be small. If the direction of transition moment is really so sensitive to environment, then obviously existing theory is far from adequate. The other possibility, namely, that the amide group is less invariant than appears from results obtained with small molecules, can only be a speculation until other evidence is forthcoming.

Angular Correlation of α-Particle and Conversion-Electron from the Decay of Ionium

IONIUM decays with the emission of α-particles leaving the final nucleus ${}^{226}_{88}\mathrm{Ra}$ at various levels of excitation known[1] to lie at 70 keV., 200 keV. and 270 keV. above its ground-state. Conversion electrons emitted from radium nuclei have been identified as due, for the most part, to *L*-conversion of 70-keV. γ-ray[2].

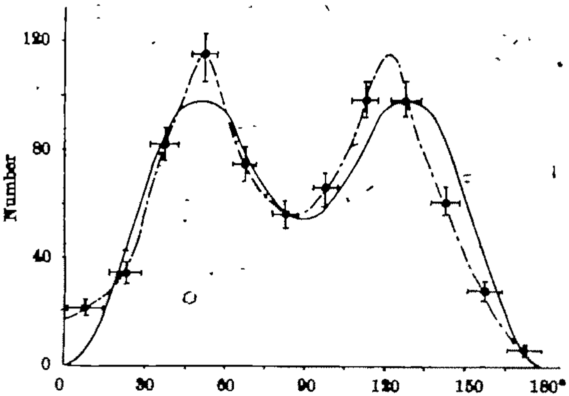
In the present experiment, we have investigated the distribution of the angles between the direction of the emission of the α-particles and of the conversion electrons by employing a continuously sensitive diffusion chamber operated at atmospheric pressure. Proper control of the vapour source, a mixture of 70 per cent ethyl alcohol and 30 per cent water, and of the gradient of the temperature, 7 deg. C./cm., gave tracks which were comparable with tracks of a Wilson chamber.

Freshly separated ionium was deposited along a wire which was fixed across the illuminated part of the chamber. The photographs, about 1,000 in all, taken at intervals of 15 sec., yielded 2,528 α-particle and 430 conversion-electron tracks. This gives 17 conversion electrons per 100 alpha disintegrations. Values obtained by different methods[1,2] were 24 per cent (Riou and also Jarvis and Ross), 11 per cent (Teillac) and 10 per cent (Albouy, Faraggi, Riou and Teillac).

Of the 430 conversion electron tracks, 336 cases could definitely be associated with α-particles. In many instances we observed electron tracks where no α-particles were to be found in the neighbourhood, although measurements of their energy showed that these unidentified electron tracks could be due to *L*-conversion of 70 keV. γ-rays.

In the accompanying graph we have plotted the distribution of the angles made by the α-particles and the conversion electrons. From the energy spectrum of the electrons observed in our experiment, it has been estimated that about 92·3 per cent are due to *L*-conversion and the remaining 7·7 per cent to *M*-conversion of 70-keV. γ-rays.

The theoretical calculations of Gellman, Griffith and Stanley[3], for the coefficients of conversion of the *L*-shell, show that most of the electrons emitted are from L_{II} and L_{III} sub-shells, while the contribution from L_{I} is negligible. Our measurements did not



Distribution of the angles between the direction of emission of the α-particles and the conversion electrons. The dotted curve gives the experimental results and the continuous curve is plotted from the expression : 54·8 – 219·2 $\cos^2\theta$ – 274 $\cos^4\theta$

permit us to separate the L_{I}, L_{II} and L_{III} electrons, as their binding energies differ only by a small amount.

It can be seen from the graph that the distribution is symmetrical about 90°, and the maxima are at 50° in the forward direction and 130° in the backward direction.

At present, no theory is available with which to compare our experimental results. The angular correlation of α-particles and *K*-conversion electron has been given by Rose, Biedenharn and Arfken[4] when the angular momentum of the intermediary state is known. If we assume[5] this to be 2, which is the angular momentum of the first excited state of the radium nucleus, then our experimental curve can best be fitted with the expression :

$$54{\cdot}8 - 219{\cdot}2\cos^2\theta - 274\cos^4\theta.$$

We are indebted to Madame I. Joliot-Curie, of the Institut de Radium, Paris, for a gift of ionium which enabled us to carry out this experiment.

Specific γ-Activity, the Branching Ratio and Half-life of Potassium-40

The specific γ-activity of ordinary potassium, in the form of 'AnalaR' potassium chloride, has been determined by the following procedure : (1) A source of potassium-42 (obtained by the irradiation of 'Specpure' potassium carbonate in the Harwell pile) was calibrated against a standard radium needle using a small carbon-walled ionization chamber. (2) The response was measured to a solution containing 1,745 gm. potassium (as 'AnalaR' potassium chloride), using a large differential high-pressure ionization chamber apparatus. (A description of this apparatus will be given elsewhere.) (3) A measured aliquot of a solution of the calibrated potassium-42 was added to the potassium chloride solution and the additional response observed as in (2). (4) The half-life of the potassium-42 was measured with the large ionization chamber apparatus and found to be (± probable error) 12·516 ± 0·007 hr. Analysis was by the method of least squares and each point on the decay curve was weighted on an experimental basis. It was necessary to correct for the presence of a small amount of unidentified long-lived activity with an apparent half-life of about 177 days. Sodium lines were reported in the spectrographic analysis, although the percentage contamination was not given ; the half-life result will therefore tend to be slightly greater than that of absolutely pure potassium-42, because of the presence of some sodium-24 of half-life 15·0 hr.

Corrections were applied for differences in attenuation in the wall of the carbon chamber between radium and potassium-42 radiations, internal absorption in the potassium-42 source and differences in the absorption of potassium-40 and potassium-42 quanta (1·46 and 1·51 MeV. respectively) in the solution and the steel walls of the ionization chambers.

In deriving the final result the following major assumptions were involved : (1) The dose-rate from a point source of 1 mgm. radium filtered in all directions by 0·5 mm. platinum is 8·2 ± 0·1 r. hr.$^{-1}$ at 1 cm. (It is believed that measurements with small carbon chambers will slightly over-estimate this constant, because of the effect of the condensed state of matter upon the electronic stopping power[1], a factor which has hitherto been disregarded. Accordingly, greater weight is given to the 'free air' determination of Taylor and Singer[3]. This problem will be discussed in detail elsewhere.) (2) The potassium-40 quantum energy is 1·46 ± 0·01 MeV.[2]. (3) The dose-rate per mC. of a point source of 1·46-MeV. radiation at 1 cm. is 7·65 ± 0·12 r. hr.$^{-1}$. (The greatest uncertainty in calculating this figure is in the value adopted for *W*, the average energy required to form one ion pair in air. This was taken to be 32·5 ± 0·5 eV.)

The value obtained for the specific γ-activity of ordinary (that is, unenriched) potassium was (± probable error) 3·37 ± 0·09 quanta sec.$^{-1}$ gm.$^{-1}$.

Evans and Evans[4], in a precise determination using as a reference source cobalt-60, calibrated by β—γ coincidences, found that 1 gm. of ordinary potassium emits 4·9 ± 0·1 MeV. sec.$^{-1}$. With 1·46 ± 0·01 MeV. as the quantum energy, their measurement yields 3·36 ± 0·07 quanta sec.$^{-1}$ gm.$^{-1}$. Other estimates include 3·6 ± 0·3[5], 3·0 and 2·95[6], 3·6 ± 0·4[7], 3·4 ± 0·5[8].

The branching ratio. Recent experiments[9,12] have demonstrated conclusively that the 1·46-MeV. γ-ray is associated with the electron-capture branch in the decay of potassium-40, and the measurements of Sawyer and Wiedenbeck suggest that perhaps all electron-capture transitions to argon-40 are accompanied by the emission of a 1·46-MeV. quantum.

Thus,

$$\frac{\lambda_\gamma}{\lambda_\beta} < \frac{\lambda\ ({}^{40}\mathrm{K} \rightarrow {}^{40}\mathrm{A})}{\lambda\ ({}^{40}\mathrm{K} \rightarrow {}^{40}\mathrm{Ca})}\ .$$

The weighted mean of the best measurements[5,10] of the specific β-activity of potassium is (± probable error) 27·4 ± 0·3 sec.$^{-1}$ gm.$^{-1}$.

Thus,

$$\frac{\lambda_\gamma}{\lambda_\beta} = \frac{3\cdot37}{27\cdot4} = 0\cdot123 \pm 0\cdot003 \text{ (} \pm \text{ probable error).}$$

Mousuf[11] measured the ratio argon-40 to potassium-40 for geological samples (assumed to be $1\cdot03 \times 10^9$ yr. old), and on the basis of a total half-life for potassium-40 of $1\cdot27 \times 10^9$ yr. obtained $\frac{\lambda\,(^{40}K \rightarrow {}^{40}A)}{\lambda\,(^{40}K \rightarrow {}^{40}Ca)} = 0\cdot053$–$0\cdot066$. There is thus a discrepancy amounting to a factor of 2 (at least) between this conclusion and that derived from the most reliable radioactivity data. It would seem likely that either the age of the samples has been over-estimated or argon-40 may have diffused out of them.

Half-life of potassium-40. If we regard all transitions of potassium-40 to argon-40 as being accompanied by the emission of a 1·46-MeV. quantum, we may assign an upper limit to the half-life of potassium-40. Nier[12] found the relative isotopic abundance of potassium-40 in ordinary potassium to be $(0\cdot0119 \pm 0\cdot0001)$ per cent; using the values for the specific β- and γ-activities quoted above, we find $T_{1/2} < (1\cdot31_5 \pm 0\cdot04) \times 10^9$ yr.

This work was carried out as part of an investigation of the radioactivity of the human body, and was supported by the Medical Research Council.

Note added in proof. In the light of recent experimental work (Valentine, J. M., *Proc. Roy. Soc.*, A, **211**, 75; 1952) and other less direct evidence, the author is of the opinion that the currently accepted value for W (see above) of 32·5 eV. may be appreciably in error and that the true value for fast electrons may be as high as $35\cdot0 \pm 0\cdot5$ eV. If this latter figure should be substantiated, the above conclusions would need to be revised as follows:

Specific γ-activity of ordinary potassium (this research) $= 3\cdot63 \pm 0\cdot10$ quanta sec.$^{-1}$ gm.$^{-1}$. Weighted mean of this and other determinations $= 3\cdot48 \pm 0\cdot08$ quanta sec.$^{-1}$ gm.$^{-1}$. Branching ratio $= 0\cdot127 \pm 0\cdot003$. Half-life of potassium 40 $< (1\cdot31 \pm 0\cdot04) \times 10^9$ yr.

Szilard and Chalmers Effect by Irradiation of Hexavalent Chromium in an Atomic Pile

MUXART *et al.*[1] found that no rapid exchange of chromium takes place between hexavalent and trivalent chromium in solution. This has later been verified by Menker and Garner[2]. Muxart *et al.* used this result for investigating a possible Szilard–Chalmers effect in dichromate irradiated by slow neutrons, and found that if an effect does exist in this case it is extremely weak.

Burgus and Kennedy[3] investigated the chemical effects accompanying the decay of manganese-51, which is transformed to chromium-51, and found that the amounts of trivalent and hexavalent chromium produced to a large extent depended on the chemical milieu. Since certain tracer experiments with chromium-51, made by irradiation of solid $CrO_4^{=}$ in a heavy water/uranium pile, indicated that tracer amounts of trivalent chromium were present, it was assumed that similar phenomena, as in the case of the decay of manganese-51, might take place by the irradiation of hexavalent chromium.

Solid CrO_3, 6 *M* chromic acid, and solid $KCrO_4$ and $K_2Cr_2O_7$ were irradiated in the pile, and the activity of trivalent and hexavalent chromium determined with the following result:

CrO_3, solid	13	per cent	± 2	trivalent	chromium	activity
6 *M* solution of CrO_3	6	„	± 1	„	„	„
K_2CrO_4, solid	14	„	± 3	„	„	„
$K_2Cr_2O_7$, solid	1·5	„	± 1	„	„	„

The limits given for the percentage activity of trivalent chromium are estimated from the deviations of single experiments.

To make sure that the trivalent chromium activity was really due to chromium-51, the decay and the absorption in aluminium of the radiation from the trivalent and hexavalent chromium specimens were compared and found to be identical. The specimens also followed the chemical reactions of chromium.

A more detailed account of the investigations will be given elsewhere.

Dependence of Glow to Arc Transitions on Cathode Surface Conditions

EARLIER workers have shown that the relative stability of glow and arc discharges on both refractory and non-refractory electrodes is seriously affected by cathode conditions such as oxide layers[1], vapour clouds[2], salt contaminations[3] and temperature[4]. However, owing to the rapid destruction by the discharge of prepared cathode surfaces, it has not been possible in the past to determine in a positive manner the effects of cathode surface condition on the glow to arc transition process.

A technique has now been developed, however, in which a glow discharge is moved electromagnetically between two parallel rod electrodes and is thus brought on to a part of the cathode having a specially prepared surface. Observation then shows whether the change in surface condition produces a glow to arc transition. For example, with clean tungsten electrodes in free air the conditions are set so that the glow discharge may be moved along the full length of the electrodes any number of times without transitions taking place. By simply placing a few grains of common salt at one point of the cathode surface and then moving the glow along the electrodes, it is found that a transition to an arc takes place at the point of contamination and that the arc reverts back to a glow when once past the region of contamination. Investigation also showed that by placing one drop of very dilute salt solution (10^{-5} gm./c.c.) on a clean cathode surface, transitions were repeatedly obtained at the point of contamination, indicating the extreme sensitivity of the discharge form to surface condition. As expected, transitions are induced by other low ionization salts, by the deposited salts from tap water and by grease contamination. Experiment showed also that transitions due to salts and grease can be induced on copper electrodes by this method of controlled contamination.

An attempt was made to induce transitions by deliberate local oxidation of both tungsten and copper, and although several methods of oxidation were employed no transitions were produced. Further experiments showed also that oxidation does not inhibit transitions taking place at a freshly cut groove. This apparent inconsequence of an oxidized surface, when contrasted with known experimental oxide effects, is most probably due to the determining effect of an already present atmospherically produced oxide layer, which, under the experimental conditions, cannot support a stable arc discharge. It is interesting to find however, that, with tungsten electrodes, layers of tungsten trioxide or tungsten powder produce transitions when operating near the transition point for clean electrodes, and that similar results are obtained with cupric oxide or copper powder on copper electrodes.

The experimental results obtained so far clearly indicate that comparable arc discharges may exist on typical thermionic or non-thermionic emitters, in agreement with other investigators[5]. The experiments also show that such arcs can be induced by minute surface contaminations and indicate, in agreement with the recent work of Prof. Llewellyn Jones[6], the important influence of surface condition upon the cathode discharge mechanism. A further investigation under oxygen-free conditions is being carried out.

I am grateful to Prof. J. M. Meek for the interest he has shown in the investigation and to Mr. W. L. Price for his experimental work. Acknowledgment is made to the Admiralty for permission to publish this note.

Velocity of Sound in Air at Low Pressures

Some recent measurements[1] of the velocity of ound over an extended range of pressures have ndicated that, while the velocity is independent of ressure down to pressures in the neighbourhood of 5 cm. mercury, a significant increase in velocity ppears as the pressure is further decreased. At cm. mercury the increase amounts to several metres er sec. In each case the measurements were made in metal tubes with audio-frequency sound. No acceptable physical explanation of this effect has been found. Because of the meteorological significance of these observations and their implication in supersonic aerodynamics, we have carried out a new determination of the velocity of sound in air at pressures down to 5 mm. mercury.

The method employed in this instance consisted of measuring the transit time of a pulsed sine wave between two condenser microphones mounted in the tube wall and separated by a distance of approximately four metres. The signals from the microphones after amplification were presented on the screen of a cathode-ray tube together with a standard ten-kilocycle timing wave-form. Time-base expansion was employed over the significant portions of the wave-forms to be measured so that it was possible to determine the transit time, approximately 12 millisec., with a precision of 1 microsec. Loudspeakers were mounted at each end of the tube and signals were transmitted from each speaker in turn, thus eliminating the effects of time delays in the microphone amplifiers.

Two tubes of different diameter were used. These were 10 metres long, so that reflexions from the distant end arrived too late to interfere with the observed signals. The loudspeakers were mounted on rubber, and tests made with the gas at a pressure of 10^{-5} mm. mercury showed that transmission along the metal wall of the tube was less than the microphone noise-level. The traces on the oscillograph screen were photographed and time-intervals computed with the aid of a travelling microscope. In order to avoid the effects of transients, measurements were made on peaks in the centre of the sine wave train.

The tube was pumped overnight at a pressure of 10^{-5} mm. mercury and filled with dry air free from carbon dioxide. The leak-rate of the tube was such that during the course of an experiment the increment of pressure was never greater than 0·02 per cent. The gas pressure was measured to 1 per cent and the temperature to 0·02 deg. C. Two series of measurements were made: one at a frequency of 250 c./s. with a tin-dipped steel tube 19·05 cm. in diameter, the other at a frequency of 1,000 c./s. with a bright steel tube 5·07 cm. in diameter.

The corrections appropriate to velocity measurements in tubes have been considered in detail by Henry[2]. The velocities observed were corrected first to 20° C., then for variation of gas imperfection[3] with pressure, attenuation and wall flexure. The velocities so corrected were plotted against the reciprocals of the square roots of the pressures, since the form of the Helmholtz–Kirchhoff tube correction predicts a linear relation between these quantities. The slight departures from linearity observed at the lowest pressures could be completely accounted for by the accommodation coefficient correction given by Henry. A least-squares fit was made for the velocity V_T in the tube as a function of the pressure p. For example, in the case of the 1,000 c./s. experiment:

$$V_T = 343{\cdot}39 \pm 0{\cdot}04 - (17{\cdot}21 \pm 0{\cdot}45)\, p^{-1/2} + (3{\cdot}34 \pm 0{\cdot}97)\, p^{-1}. \quad (1)$$

The value of the free-space velocity at 20° C. is thus 343·39 ± 0 04 metres sec.$^{-1}$; the corresponding value for 250 c./s. is 343·42 ± 0·13 metres sec.$^{-1}$. The generally accepted value[3] for 20° C. is 343·42 ± 0·07 metres sec.$^{-1}$.

The Helmholtz–Kirchhoff tube correction may be written

$$V_T = V\left(1 - \frac{c}{r\sqrt{np}}\right), \qquad (2)$$

where V is the free-space velocity, r is the tube radius, n is the frequency, and c is a theoretical coefficient determined by the physical characteristics of the gas.

The coefficient of $p^{-1/2}$ in equation (1) leads to a value of c which is (90·7 ± 2·7) per cent of the theoretical value. The corresponding constant for 250 c./s. is (93·5 ± 17) per cent of the theoretical value. These values are in accord with those found by Kaye and Sherratt[4] and Norton[5] at atmospheric pressure.

The coefficient of p^{-1} in equation (1) leads to a value of accommodation coefficient $f = 0{\cdot}34^{+0{\cdot}11}_{-0{\cdot}07}$. This value of f is consistent with the data for the 250 c./s. experiments for the lowest pressures.

It appears, therefore, that the tube corrections given by Henry account for the observations with an accuracy of 1 in 4,000 (1,000 c./s.) and 1 in 3,000 (250 c./s.) over the whole range of pressure studied. Down to pressures of 5 mm. mercury there is no variation with pressure of the free-space velocity for the frequencies studied.

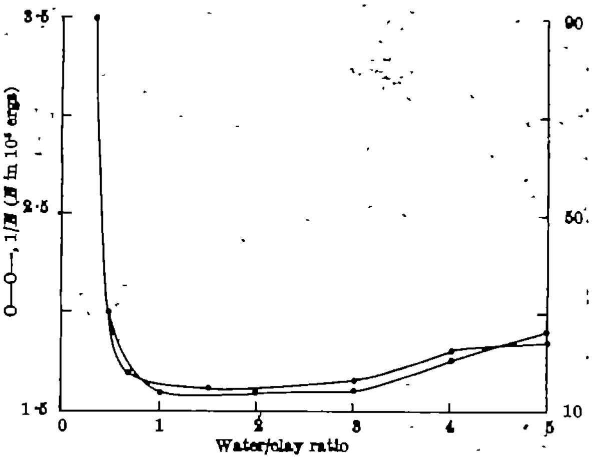
Method of Analysing Flow of Granular Materials such as Sand

I HAVE been studying the flow of foundry moulding sand, and in the course of this work have developed a conception of flow of granulated aggregates which appears to simplify the problem and to permit relatively simple flow calculations. It is possible that these ideas might help in the treatment of data obtained for the flow of materials other than foundry moulding sands.

Foundry moulding sand may be briefly described as aggregates of clay-coated silica grains to which additions of coal dust, pitch and other organic materials can be made.

It has been found useful to consider flow in terms of the energy e used to coagulate an initially dispersed unit mass of sand, and E the energy required to re-disperse or separate the grains again. The mathematical expression of flow is then based on the assumption that the energy needed to cause flow is used only in uniting and separating the grains.

The following is an example of the application of the idea to the flow of a sand through a sieve. A mass M of the material in the loose uncoagulated state is dropped from a height h on to a sieve. Some of the material is compacted on the sieve and is afterwards forced through the sieve by the remainder of the sand falling on it. Let the amount passing through the sieve be m, then:



$$MgH = Me + mE,$$

but

$$e = f(D).$$

Where D characterizes the dimensions of the sieve and is constant for any particular sieve:

$$m \propto 1/E.$$

The accompanying illustration demonstrates the validity of this treatment. The values for E were obtained by the separation of two relatively large surfaces bonded with clay/water mixtures. These values are compared with values of m, obtained by dropping sand, bonded with the same range of clay/water mixture, from a fixed height on to a sieve and weighing the material passing through the sieve. The similarity of the two curves is clearly apparent.

The procedure outlined above can be used for determining the flow of granulated materials in various circumstances. I have examined the disintegration of agglomerates under impact, the behaviour of sand when propelled by a stream of air and flow of sand during a moulding operation. In each case the use of the principle has permitted an analysis which has good correlation with experiment.

Differential Thermobalance: a New Research Tool

THERE are many models of thermobalances for making the curves, $p = f(t)$, of the loss of weight of a sample during heating. These suffer from the disadvantage that, if they are made automatic by an optical recording device, they sometimes produce records too small to display with sufficient precision the onset of reactions accompanied by a small loss of weight.

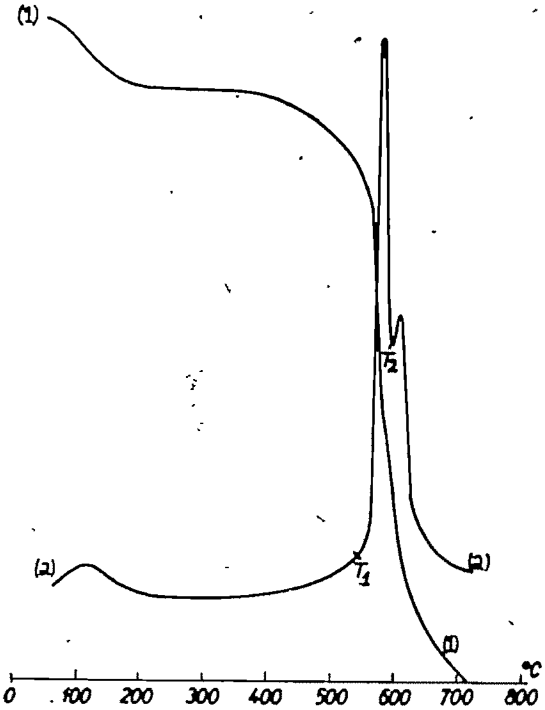
I have devised an apparatus which produces directly photographic records of the derivative

$$\frac{dp}{dt} = f'(t).$$

The differential, while giving a greater precision than integral curves, allows the results to be presented on a smaller scale. The accompanying figure shows the value of the method. Curve 1 is $p = f(t)$ for a mixture of 90 per cent kaolin of Zettlitz and 10 per cent diaspore. Curve 2 is the differential curve obtained by the new method. It is clear that the onset of the dehydration of diaspore (temperature T_1) is scarcely visible on the integral curve, although it is very clear on the differential. The curves thus obtained can be compared with those of differential thermal analysis and can be used alongside the latter. By comparing the results of the two methods it is, in fact, possible to distinguish peaks due to loss of weight from those which are due to endothermic reactions of another nature.

So far as the loss of weight is concerned, the advantage of the differential thermogravimetry over differential thermal analysis is that it is quantitative. Indeed, the loss of weight corresponding to each peak is proportional to the area contained between the curve and the abscissa. Because of this, it is possible to calculate, rather approximately, the composition of a mixture of various minerals. The advantage over ordinary thermogravimetry is that recording is easier and the precision is greater.

The automatic apparatus constructed by me consists essentially of two tubular electric ovens, a balance, an optical system and a drum for recording photographically curves such as (2) in the figure. During the analysis, the temperature of the two ovens is gradually raised, one being kept at a temperature 4 deg. C. lower than the other. On the trays of the balance are hung crucibles containing exactly equal quantities of the substance to be analysed. These crucibles, hanging in the ovens described above, are always at temperatures differing by 4 deg. C. By means of a mirror attached to the beam of the balance, it is possible, by a suitable optical system, to register the derivative dp/dt as a function of time (which is itself proportional to the increase of temperature).



Curve (1), $\Delta p = f(t)$; curve (2), $\Delta p/\Delta t = f'(t)$

Comparative Philology and the 'Kon-Tiki' Theory

Neither in Mr. Heyerdahl's book[1], nor in Prof. Raymond Firth's review of it[2], is there any indication of the relevant philological state of affairs[3]. Yet, in considering whether the Polynesians came from America or from Asia, comparative philology affords an absolutely decisive disproof of Mr. Heyerdahl's theory. The evidence is easily put concisely in a set of three statements, namely:

(1) Two languages are defined as related if, and only if, they were once one language; thus French and Spanish are related because, and only because, they were once Latin[4].

(2) If we develop statement (1), we readily reach the concepts (*a*) family of languages; (*b*) parent language; (*c*) related families of languages. Thus French, Spanish, Italian, etc., form the Romance family of which Latin is the parent; English, German, Dutch, etc., form the Germanic family of which 'Primitive Germanic'[5] is the parent; we may also say that Romance and Germanic are related, meaning thereby that their parent languages, Latin and Primitive Germanic, are related because they were once one language, Primitive Indoeuropean.

(3) It is accepted by philologists (*a*) that Polynesian is related to Indonesian[6] and (*b*) that no relationship subsists between Polynesian and any American language-family.

Two further points call for comment.

(*a*) The determination of linguistic relationship is a highly technical matter, requiring many years prior training in the rigid, algebra-like discipline of some specific branch of comparative philology (for example, that of Indoeuropean, Finno-Ugrian or Indonesian). Linguistic relationship is therefore not a subject on which the non-specialist is entitled to his own opinion.

(*b*) The chronology is of interest. Mr. Heyerdahl postulates two waves of 'Polynesians' coming from America, the first c. A.D. 500 from Peru, the second c. A.D. 1000 from north-west North America. But we possess written texts in Old Javanese (an Indonesian language) of at least the eighth century A.D.; the period during which Primitive Indonesian was spoken obviously antedates these texts considerably.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

DEPUTY, Principal Scientific Officer grade (with first- or second-class honours degree or equivalent in physics or chemistry, and a proven interest in biological problems), at the Ministry of Supply Research Establishment, Field Trials Section, Salisbury, to design and supervise highly specialised forms of field trials—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A200/53A (August 29).

LECTURER IN THE DEPARTMENT OF ORGANIC CHEMISTRY—The Registrar, The University, Bristol, 8 (September 1).

ASSISTANT LECTURER IN APPLIED CHEMISTRY and an ASSISTANT LECTURER IN MATHEMATICS—The Registrar, College of Technology, Manchester 1 (September 7).

SCIENTIFIC OFFICER (with university degree in science or agriculture, and preferably with special qualifications in agricultural entomology) IN THE AGRICULTURAL ENTOMOLOGY RESEARCH DIVISION of the Ministry of Agriculture, to assist in advisory work and to carry out entomological research in connexion with the control of insect and allied pests of crops and livestock—The Secretary, Civil Service Commission, Stormont, Belfast, N. Ireland (September 7).

RESEARCH FELLOW (Junior) IN SOCIAL PSYCHOLOGY—The Secretary, The University, Aberdeen (September 12).

SCIENTIFIC OFFICER (with good honours degree (chemistry) and preferably with research experience) AT THE UNIT OF PLANT NUTRITION, Long Ashton Research Station, Bristol, for work on chemical problems concerned with the mineral nutrient status of plants, particularly trace elements—The Secretary, Agricultural Research Council, 15 Regent Street, London, S.W.1 (September 12).

ENGINEERS and PHYSICISTS (with first- or second-class honours degree or equivalent in electrical engineering or physics) IN THE ELECTRONICS DIVISION, Atomic Energy Research Establishment, Harwell, for duties ranging from fundamental research on circuitry and the physics of nuclear radiation detectors, to devising and developing (often in collaboration with industry) electronic devices for Atomic Energy Project—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.195/53A (September 12).

LECTURER IN MECHANICAL ENGINEERING—The Registrar, The University, Sheffield (September 14).

LECTURER IN PHYSIOLOGY (graduate in medicine or science, and with postgraduate experience in some branch of physiology) at the University of Birmingham—The Assistant Registrar, Medical School, Birmingham 15 (September 15).

READER IN ANTHROPOLOGY at the London School of Economics and Political Science—The Academic Registrar, University of London, Senate House, London, W.C.1 (September 15).

RESEARCH FELLOW (with honours degree in physics) to undertake radio-isotope research in connexion with urological problems, especially those connected with urological malignant disease—The Registrar, The University, Leeds 2 (September 16).

RESEARCH OFFICERS (2), (*a*) (with university honours degree in agricultural science, or science, with specialization in agronomy or allied work, and preferably with postgraduate experience) to undertake research on pasture and crop establishment and development under irrigation, particularly on soils of heavy texture (Ref. 132/38); (*b*) (with honours degree in civil engineering, agricultural science, or science, with physics or geology as a major subject, or equivalent qualifications) to undertake research into the influence of irrigation and other practices on the hydrologic cycle especially on ground water table levels (Ref. 132/39), at the Commonwealth Scientific and Industrial Research Organization, Division of Plant Industry Regional Station, Deniliquin, New South Wales, Australia.—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting the appropriate Ref. No. (September 19).

CIVIL ENGINEER (with at least 10 years experience in the design of civil engineering work and particularly reinforced concrete structures) (Ref. TT/675); ASSISTANT CIVIL ENGINEER (with experience in the design and detailing of reinforced concrete structures) (Ref. TT/676)—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, quoting appropriate Ref. No. (September 29).

DIRECTOR OF AGRICULTURE, Western Samoa, to take charge of the Department of Agriculture and advise the Government in the formulation of its agricultural policy and be responsible to the High Commissioner for all matters connected with its application—The Public Service Commissioner, Apia, Western Samoa (September 30).

PROFESSOR OF GEOLOGY at the Victoria University College, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (October 1).

PROFESSOR OF MUNICIPAL ENGINEERING—The Registrar, College of Technology, Manchester 1 (October 1).

LECTURER IN BACTERIOLOGY at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (October 2).

SENIOR LECTURER IN PSYCHOLOGY (preferably with qualifications in medicine, particularly psychological medicine) at the University of Melbourne, Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (October 15).

CIVIL ENGINEERING ASSISTANTS IN THE WORKS DEPARTMENT at Admiralty establishments at Sheerness, Chatham, Yeovilton, Devonport, Culdrose, Leeds, Belfast and Rosyth—Civil Engineering Chief, Admiralty, Chamberlain Way, Pinner, Middlesex.

GOVERNMENT CHEMIST and an ASSISTANT GOVERNMENT CHEMIST in the Colonial Chemical Departments of (*a*) Uganda (Ref. CDE 97/9/01); (*b*) Nigeria (Ref. CDE 97/14/01)—The Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting appropriate Ref. No.

LECTURER IN DAIRYING (with qualifications in dairying or agricultural science, or science (chemistry and bacteriology)) at the School of Agriculture, Sutton Bonnington—The Registrar, The University Nottingham.

PHYSICIST (with university degree or equivalent qualification) for research on electric arc furnace problems (Ref. "Arc Furnaces"); APPLIED PHYSICISTS and RESEARCH ENGINEERS, senior and junior (candidates for senior posts should have an honours degree and two to three years research experience, and for junior appointments a degree or equivalent qualification) for research in industrial metal working processes, such as rolling and forging (Ref. "Metal Working"); and a PHYSICAL METALLURGIST (with university degree or equivalent) to carry out research on the ageing of mild steel (Ref. "Ageing of Steel") in the Sheffield Laboratories—The Personnel Officer, British Iron and Steel Research Association, 11 Park Lane, London, W.1, quoting appropriate Ref. No.

PHYSICISTS, SCIENTIFIC OFFICERS (with first- or second-class honours degree or equivalent) or EXPERIMENTAL OFFICERS (with H.S.C. (Science) or equivalent) at Ministry of Supply Research and Development Establishments at Malvern, Farnborough, Sevenoaks and other out-stations in Southern England, for work on aerodynamics and aircraft structures; armaments; instrumentation; radio and radar—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.170/53A.

PHYSIOLOGIST (with good honours degree in physiology or equivalent, and preferably with research experience involving the perfusion of isolated organs) for research on the physiology of lactation—The Secretary, National Institute for Research in Dairying, Shinfield, Reading, quoting 53/3.

PHYSIOLOGIST (with honours degree in physiology and three or more years experience in physiological research) to undertake experimental work on the alimentary tract of the ruminant—The Secretary, Rowett Research Institute, Bucksburn, Aberdeenshire.

STATISTICAL METHOD IN BIOLOGICAL ASSAY

D. J. Finney, M.A., Sc.D.
Lecturer in the Design and Analysis of Scientific Experiment, University of Oxford

A comprehensive account of designs and statistical analysis for biological assays, both as a textbook for the student of statistics and as a work of reference for the practitioner of bioassay.
Pp. xx + 661. (9 in. × 6 in.) Price **68s.** net

A STATISTICAL PRIMER

F. N. David, D.Sc.
Reader in Statistics, University of London

A knowledge of simple statistical ideas is to-day essential in most fields of research, and the scientist and research worker, together with the student of statistics, will welcome this new book, which proves that an advanced knowledge of mathematics is unnecessary to master the elements of statistics.

DISCIPLINE AND LIBERTY WITHIN THE SOCIAL SYSTEM

PROF. F. A. HAYEK has now brought together a series of studies on science and the study of society first published in *Economica* during 1942–44, the essays on L'École Polytechnique which Saint-Simon and Comte and their successors published under the title "The Counter-Revolution of Science" in the same periodical in 1941, and a later study of Comte and Hegel published in *Measure* of June 1951*. The last study, of the extent to which the characteristic approach of our age to sociology is due to the agreement in thought between Hegel and Comte, and the influence of their ideas on social theory, is indeed a natural sequence to those studies of the influence of the École Polytechnique of Saint-Simon and Comte in Britain and Germany as well as in France, which constitute the second part of the book. Both studies attribute the totalitarianism of the twentieth century to the ideas of Hegel and Comte, of Feuerbach and Marx. This examination of the historical role of the abstract ideas described in the first part of the book is lucid and well written ; but Prof. Hayek's exposition is scarcely less lucid when he is handling the more abstract or theoretical discussion of the general issues, though some chapters are more readable than others. Indeed, his book has, in fact, a far wider interest than its philosophical approach would suggest, and its close bearing on some of the most important questions of the day should commend it to a much wider circle of readers than professional philosophers or economists.

The central theme of the book is that many of our present difficulties are due to a misinterpretation of the lesson which the conquest of Nature by science and technology has for the ordering of our affairs. Analysing the position which man holds in relation to Nature on one hand, and to the products of his mind on the other, Prof. Hayek urges that the application of some of the concepts and methods of the physical sciences to the interpretation of social problems can lead to serious errors. In essence, his book is a reasoned protest against the mechanical and uncritical application of habits of thought to fields different from those in which they have been formed, and more especially against the application of those methods and ways of thinking developed by the disciplines of the physical and biological sciences to subjects like social studies.

At some points Prof. Hayek's account of the problem and method of the natural sciences may be open to challenge ; but his interpretation of the way in which these differ from what is encountered in the social sciences, and of the consequences which follow from attempts to treat the problems of the social services after the fashion of the natural sciences, provide a firm basis for his well-known opposition to social or economic planning in general. Further, this analysis, which suggests the sub-title of the book—"Studies in the Abuse of Reason"—gives a strong hint as to the real cause of difficulties in large-scale organization to-day which are commonly overlooked in discussions on nationalization and other aspects of what is termed the Welfare State. "We flatter ourselves undeservedly," writes Prof. Hayek, "if we represent human civilization as entirely the product of conscious reason or as the product of human design, or when we assume that it is necessarily in our power deliberately to re-create or to maintain what we have built without knowing what we are doing. Many of the greatest things man has achieved are not the result of consciously directed thought and still less the product of a deliberately co-ordinated effort of many individuals, but of a process in which the individual plays a part which he can never fully understand. They are greater than any individual precisely because they result from the combination of knowledge more extensive than a single mind can master."

---

* The Counter-Revolution of Science: Studies on the Abuse of Reason. By F. A. Hayek. Pp. 255. (Glencoe, Ill.: The Free Press; London: George Allen and Unwin, Ltd., 1952.) 32s. net.

Prof. Hayek could with some justice have equally sub-titled his book "Studies in the Meaning of Freedom", for in this central passage he comes very near to explaining why, in spite of the demand for 'conscious' control or direction of social processes which is so characteristic of our generation, we can only begin to enjoy freedom when we recognize the limitations of the powers of individual freedom. Failure to do so, and the persistent increase in the demands which are placed on the individuals responsible for directing organizations we create, can only result in breakdown or chaos in the absence of the supermen needed to run them. Ultimately—and not in such a very long run—what is politically possible must be determined less by political desires than by the mental and physical, if not also the moral, capacities of individual men and women.

So far from believing that consciously directed processes are necessarily superior to any spontaneous processes, Hayek agrees rather with A. N. Whitehead that "civilization advances by extending the number of important operations we can perform without thinking about them at all"; and there is a suggestive resemblance between his approach to social planning and organization and the conditions generally accepted as conducive to creative work in any field. Part at least of the importance of this stout championship of individualism lies not so much in its showing that the present tendency to attempt to extend conscious control of society leads straight to totalitarianism as in its support of the moral fabric of civilization. "Any general refusal," comments Hayek, "to accept existing moral rules merely because their expediency has not been rationally demonstrated is to destroy one of the bases of our civilisation." In rejecting planning, Hayek is not advocating chaos or anarchy but urging discipline. His insistence on the need for a rational comprehension of the limitations of human reason leads him to a very similar position to that which Dr. K. E. Barlow reached in a very different way in "The Discipline of Peace" much about the same time Prof. Hayek originally prepared these studies. Not merely the advance but also the very preservation of civilization depend on our obedience to principles which we do not fully understand—the acceptance of existing moral rules and traditions. Hayek's plea that we should be concerned that we do not destroy the foundations of existing structures before we are sure that those of the institutions to succeed them are truly laid is dignified and forceful, and one to be heeded to-day in education and elsewhere.

Scientists themselves are probably now more disposed to recognize the limitations of science and less prone to apply their methods and mental habits in fields where they are not competent than they were when Hayek prepared these essays. But to turn back to Dr. Barlow's plea for discipline is to realize how little progress has been made in the past decade towards achieving an order in which personal liberty and personal discipline fit harmoniously, or towards recognizing that the primary issue is not how we are to treat materials, but how men are to treat each other and the life of the earth which endows them. The real task is still one of education.

On this, too, Barlow and Hayek agree. Barlow remarked, for example, on the need for man to understand as well as to enforce the discipline under which he must live, and on the necessity for such understanding for the existence of initiative and liberty within a social system; while Hayek's insistence on the limitations of reason and of conscious control implies that the determining factor in unconscious control and in securing the efficient use of our resources is the ability and understanding of those individuals of which a society is composed. Hayek, too, suggests that the great misfortune of our generation is that the direction which the amazing progress of the natural sciences has given to its interests is not one which assists us to comprehend the larger process of which as individuals we form merely a part, or to appreciate how constantly we contribute to a common effort without either directing it or submitting to the orders of others. His chapter "Engineers and Planners" is entirely relevant to the current discussions on technological education in Great Britain and on the purpose of university education; and he regards the failure to convey awareness of being part of a social process, and of the manner in which individual efforts interact, as one of the great weaknesses of an education limited to the sciences or to technology. The engineer's job, he points out, is not complete in itself, nor is it easy to assemble all the widely dispersed knowledge required. There is a problem of co-operation in which the existence of a gulf between different types of mind may be vitally important.

PLANT DISEASES

Plant Diseases

By Dr. F. T. Brooks. Second edition. Pp. xiii+458. (London, New York and Toronto: Oxford University Press, 1953.) 38s. net.

It is gratifying to see, after the lapse of nearly a quarter-century, that a new edition of the late Prof. F. T. Brooks's book on plant diseases has been produced. While the style and scope of the new volume (the greater bulk of which discusses a large number of specific diseases) remain much the same as in the first edition of 1928, additional matter has been included without increasing the thickness of the book, by the adoption of smaller print and thinner paper.

The first edition has been completely re-written, and a few more illustrations have been added. An exceedingly valuable and all too brief introductory section on the various aspects of plant disease is succeeded by a short chapter on non-parasitic diseases which, the late author points out, is only an introduction to this big group of plant maladies; a short section, again all too brief, on virus diseases completes all the information of a general nature before the reader comes, in the third chapter, to the accounts of specific diseases, occupying eighteen chapters of the book, which closes with a section on fungicides. An excellent feature, on which much care and labour have been expended, is the list of references at the end of each of the twenty-two chapters, all of which, with the exception of the first three, are devoted primarily to British plant diseases together with others of importance wherever they occur, including also those of tropical crops.

Valuable though the late Prof. Brooks's new edition will prove to all interested in plant diseases, one feels that this distinguished mycologist and teacher would also have served with equal distinction in his capacity as general editor to a more comprehensive volume dealing at greater length only with the general principles of his subject. With the rapid expansion in our knowledge of plant pathology during recent years, despite the production of valuable manuals at the hands of numerous specialists, there is a strong feeling among teachers, students and research workers alike of the need for greater co-ordination of this extensive new material so as to present in a general way the various aspects and factors relative to disease. To this end, one regrets that the collaboration which the late author had sought did not fully materialize; and with the wealth of talent so close to his hand and of those whom he mentions in his preface to the new volume, all of them specialists of wide experience in their diverse spheres, one feels that such a comprehensive collective work on the general principles of plant pathology would not only have proved of inestimable value to both teacher and student, but would also now remain as another edifice to the worthy memory of a master scientist and teacher.

S. G. JONES

CONSEQUENCES OF ATOMIC POWER

Atomic Power

An Economic and Social Analysis; a Study in Industrial Location and Regional Economic Development. By Walter Isard and Vincent Whitney. Pp. xi+235. (London: George Allen and Unwin, Ltd., 1952.) 37s. 6d. net.

OUR grandparents, while great believers in progress through diligence and thrift, seem to have doubted the possibility of a substantial improvement in the lot of the majority of mankind. This attitude was challenged by the radicals, and between the two World Wars it gradually became old-fashioned not to believe that nationalization and the planned use of all natural resources would introduce an age of peace and plenty. Since the Second World War, however, it has begun to be whispered that natural resources look a bit inadequate compared with even the foreseeable demands of a steadily increasing world population. In this dilemma the latest bolus proffered to us is the promise of cheap and unlimited nuclear power for industry.

The authors of this book (respectively an economist and a sociologist) examine the technical, economic and social problems associated with atomic power and reach a number of very interesting conclusions.

In the first place, the authors think that in the foreseeable future nuclear power is unlikely to be cheaper than, or even as cheap as, power from conventional energy sources. The best available figures suggest that the capital cost of a nuclear power station will be at least double that of the equivalent coal-fired station; since the nuclear plant may have a shorter life, the *annual* capital charges will be up by an even greater factor, and in these circumstances the nuclear plant is not competitive. This situation may, of course, improve.

Second, the authors think that the influence even of low-cost nuclear power on the location of industry, on industrial output and on standards of living will be much smaller than is often supposed. In the manufacturing industries, the ratio of the cost of fuel and purchased energy to both the value of the product and the value added in manufacture is usually quite small, and if power cost nothing the direct effect on output and costs would not be great. The main factors influencing the location of industries are proximity to raw materials and to markets; the availability of water, food, labour and capital; the proximity of other industries, the momentum of an early start and a favourable climate. Only a few industries are definitely power-oriented; atomic power does not remove the many other determinants of industrial location.

Third, the authors think that nuclear power, if and when it comes, is most likely to benefit advanced industrial communities and may place industrially backward nations at a greater disadvantage than they are to-day. For example, when capital costs are high, areas in which interest rates are high are at a disadvantage relative to areas in which interest rates are low.

If there are economies of scale, areas where the power demand is large should be able to obtain power at lower prices than areas where there is only a small unfolding demand. Furthermore, just these latter areas are apt to be short of capital to finance the industrial expansion that would cheapen power.

Considerations such as these obviously place the economically under-developed nations at a general disadvantage so far as access to nuclear power is concerned. This disadvantage is accentuated by their lesser ability to provide the special skills and industrial facilities likely to be required by nuclear power plants.

It is interesting to note that the authors suggest that the U.S.S.R. may have more to gain from atomic power than the United States. "Relative to the U.S.A., Soviet energy resources no matter how stated are inferior, and the areas within the country in which fuel and energy resources are critically short are more numerous. On the other hand Russia's more rapid growth of population, the associated greater mobility of its labour force, its more rapidly expanding market, and its less mature economy, which is conducive to fuller utilization of major innovations, all point to the probability that Russia will be able to exploit a new energy resource such as atomic power most effectively and extensively. It is not merely that Russia can; it is also that the believed necessity to do so is greater."

The first 23 pages of the book deal with the technical background of atomic power. This section gives a fair survey of the field. There is, however, a lack of emphasis which leaves a reader in some doubt about the relative importance of the various topics touched on.

The second part of the book (108 pages) is devoted to costs and industrial applications. The five chapter headings are: the costs of atomic power; atomic power and location theory; atomic power and the location of specific industries; the iron and steel industry; the aluminium industry. All these matters are discussed in a competent, informative and interesting way.

The third part of the book (76 pages) deals with atomic power in relation to the process of regional economic development, and considers its possible impact upon regional economies in various stages of such development. Particular attention is given to the cultural resistances which impede the introduction of new ideas and techniques, and Brazil is taken as a case study. The fourth part (5 pages) is a summing up.

This book is obviously the outcome of considerable research and reflexion, is well written and attractively printed. It can be recommended without reservations to all persons interested in the future of atomic power.

B. L. GOODLET

FOREST MANAGEMENT

Planned Management of Forests

By N. V. Brasnett. Pp. 238. (London: George Allen and Unwin, Ltd., 1953.) 20*s*. net.

THE nature of forests is such that their management requires long-term planning if their productivity is to be increased progressively or indeed maintained. It is the absence of management in this sense that is the usual reason for the impoverishment and, in many instances, destruction of forest which still continues in many parts of the world. The problems of long-term development of forests to secure maximum and sustained production were first tackled in France and Germany, and in the course of time various management techniques have been developed which are appropriate in various degrees to the conditions in these and other European countries. The current techniques, however, may not be applicable to forests in other parts of the world that are only now coming under management for the first time, although some crude method used earlier in Europe may be appropriate. Students trained in the university forestry departments in Britain go to all parts of the British Commonwealth, and have to deal with forests in all stages of development and intensity of management. Merely to teach them the current European techniques will only result in their frustration when they meet conditions to which they are not applicable.

A merit of this book is that it attempts to deal with this problem. While of necessity most of the book deals with European methods and conditions, it does so historically, and the special problems, particularly of tropical forests, now coming under systematic management for the first time are discussed. The special case of the United Kingdom, in so far as afforestation schemes are concerned, is mentioned but not developed. The student, however, should grasp that the type of management must be devised to meet the conditions prevailing, although the ultimate ideal may be the same everywhere.

The book is divided into three parts. Part 1 deals with basic considerations, such as the growing stock, increment, rotations, and the organization of the forest into different management units. Part 2 deals with the preparation of working plans. The general form and order is that suggested by the late Mr. Ray Bourne and now generally followed in Britain. All the usual methods of yield regulation are discussed. Brandis's method, first evolved in 1856 in Burma, is given a good deal of space, because it still has a place in some tropical forests. Brief reference is made to regulation by tending or cutting class as practised in Sweden. This might usefully have been developed more fully, because it has possible applications in similar forest types within the Commonwealth. Part 3 is entitled "Development of Forest Management in Western Europe". This is an interesting and concise review. Because, however, the same topics are in part discussed in both Parts 1 and 2, a good deal of forward as well as back referencing has been necessary, and in any future edition it would be worth while considering whether some rearrangement of the subject-matter would obviate this.

The book is designed primarily for the university forestry student; but it will require elaboration by his teacher in places. One defect is that there are no literature references, and at least a selected bibliography would have increased its value for this type of reader. The intelligent layman who wants to know about the problems of forest management will find this a useful book, because it is both lucid and readable.

H. M. STEVEN

UNDERWATER EXPLORATION BY 'AQUALUNG'

The Silent World

By J. Y. Cousteau with Frédéric Dumas. Pp. xi+148+65 plates. (London: Hamish Hamilton, Ltd., 1953.) 18*s*. net.

CAPTAIN COUSTEAU, who is at present leading an oceanographic expedition sponsored by the French Navy and the French Centre for Research and Oceanographic Studies, is a world authority on free deep-sea diving. With the development of his 'aqualung', a self-contained compressed-air unit with an automatic flow regulator, he has greatly enlarged the scope of underwater exploration and research with this apparatus, descents down to 300 ft. can be undertaken without the aid of any other special equipment or clothing.

Among the accounts in "The Silent World" of the varied investigations undertaken by Captain Cousteau and his team of divers, of special interest are those relating to the exploration of the inland cave at the Fountain of Vacluse near Avignon; the surveys of numerous sunken ships in search of data on their biological incrustation; the effects of underwater explosions; and participation in 1948 in the preliminary trials of Prof. Auguste Piccard's 'Bathyscaphe'. Interspersed with these accounts are interesting comments on some of the physiological problems associated with diving, such as the effects of cold on the human body, on 'the bends', and the related nitrogen narcosis which produces deep-sea rapture (*l'ivresse des grandes profondeurs*).

Two valuable impressions emerge from reading this book, impressions which should encourage marine (and possibly freshwater) biologists to add this wonderful tool, the 'aqualung', to their research equipment. These are, first, the ease and degree of safety with which the equipment can be used, even by the non-swimmer, and secondly, the removal of at least some of the apprehensions and fears which intending divers may have about encounters with the traditional terrors of the deep, the barracuda, the giant rays, the octopus and even the shark.

In an epilogue to the book, the author answers the question which must have been put to him many times, "Why in the world do you want to go down into the sea?". Apart from being obsessed by a desire to explore the unknown, he believes that man must of necessity turn his attentions more and more to a study of the seas, to explore them intimately and draw sustenance in the form of minerals, chemicals and food from this vast, untouched 'cornucopia'. For this reason he urges the development of diving equipment capable of being used for exploring much greater depths than can his own 'aqualung', which he modestly dismisses as "primitive and unworthy of contemporary levels of science".

The book is lavishly illustrated with underwater photographs, many of which are in colour, and although essentially 'popular', it nevertheless contains much of interest to the hydrobiologist.

A. J. Brook

CALCULATING MACHINES

Les machines à penser

Par Louis Couffignal. Pp. 158+4 plates. (Paris: Le Éditions de Minuit, 1952.) n.p.

THE development of large and complex electronic computing machines naturally excites a great deal of popular interest. Words such as memory, decision, instruction, information and language are often used in descriptions of these machines. There are strong objections to the use of such anthropomorphic notions as that electronic digital computors possess rudimentary powers of scholarship, volition or reasoning (see, for example, Kapp, R. O., *Nature*, 170, 547; 1952). But it really all reduces to the definitions used. The meaning of such definitions would be unnecessarily narrowed down and their pictorial power lost if processes like memory or reasoning were attributed solely to human beings.

Louis Couffignal is not afraid of using anthropomorphic terms, provided it is understood that the machines achieve the same ends by quite different means. The book opens with definitions of a machine and of thought. If one defines a machine as an assembly of objects which are put together in such a way that they replace man in the execution of a set of operations proposed by man, then, naturally, even the simple adding machine possesses a rudimentary memory and its mechanism of 'carry-over' replaces quite a complex set of mental operations of a human brain.

A description of adding machines and punched-card machines follows. It does not go into great technical detail of the machines themselves, but is sufficient to convey a general idea of their capabilities. The description of the universal machines deals with Babbage's ideas, with Mark I of Prof. Aitken, ENIAC, and a machine built at the Institut Blaise Pascal. The advantages of the binary system are clearly shown; its adoption leads to the reduction of the size of a large machine of a given capacity to about a third—a very considerable saving. The operations of multiplication, division and square-root extraction, using the binary system, are well explained. The next chapter is concerned with analogue machines, such as the differential analyser of Vanevar Bush; it is a pity that the electronic analogue machines, such as Pepinsky's X-RAC, are not mentioned.

The chapter dealing with the nervous system is rather superficial; one has the feeling that the writer is not in his own field here. Surely modern work on giant nerve fibres of squids and the permeability changes of the nerve membranes to potassium and sodium ions could have been included. The analogy between the transistor and a synapsis may not be as close as the author seems to believe.

In the chapter on the mechanization of logic the author, who is the director of the computing laboratory of the Institut Blaise Pascal, is much more in his element. The expression of logic in a binary system is of great interest, although rather heavy going for a lay reader. It took me some time to discover what the symbol 0010.0100 for a logic function (p. 105) really means and what is the significance of the dot in the symbol. Further confusion results from designations of "prédicats" P_n by a capital letter on p. 104, by a lower-case p_n on p. 112 and a capital in Fig. 25. Further, a function $p_n = 0000.1111$ on p. 109 has n as a subscript, and p^{n+1} on p. 114 has it as a superscript, without adequate explanation. However, these are only minor defects which do not detract from the value of the book as a suitable introduction to the subject.

The book finishes with, not conclusions, but a programme of research, stimulated by the close analogies between processes of human thought and modes of action of modern computing machines. There are no references and no subject index.

FOOD FOR THE WORLD

The White Man's Dilemma

Food and the Future. By Lord Boyd-Orr; with the co-operation of David Lubbock. Pp. 124. (London: George Allen and Unwin, Ltd., 1953.) 9s. 6d. net.

THE connecting link between the title and sub-title of this new survey of food problems by the first director-general of the United Nations Food and Agriculture Organization is the concept that food is the foundation of social security and economic prosperity; that hunger has been the basis of most revolutions; and that hunger is at the root of the present revolt of Asia. Throughout the book runs Lord Boyd-Orr's strong conviction that there will never be world peace until there is no more hunger. The dilemma which he poses for the white man is the choice between attempting to maintain world military and economic supremacy, with the probable result of a disastrous world war which would end Western civilization, or using his present industrial superiority to develop the resources of the earth so as to end hunger and poverty, a course which would lead to the loss of the white man's world control gained by three centuries of conquest. As Lord Boyd-Orr says, this is a hard choice.

The section on world population trends quotes the already familiar estimate that this may increase from the present 2,400 to 4,000 million by the end of this century, but reaches an unusually optimistic conclusion that the limit will finally be set at between 4,000 and 6,000 million, after which world population will decline. Lord Boyd-Orr argues that the under-developed nations at present approaching the rapid population expansion experienced in England and Wales in the nineteenth century will, when their standard of living and education rises, begin the gradual decline in population growth now in progress in Western Europe. This leads him in his discussion on the agricultural potentialities of the world to the equally optimistic conclusion that "There seems no reason to doubt the estimate made by agricultural experts, that if modern improved methods were applied to all the land at present cultivated or grazed the world food supply would be doubled, and that if known measures were taken to increase the area of the earth under cultivation by irrigation, bush clearance, and other measures, the earth could support a population of 6,000 million". Before reaching this conclusion, he reviews the problem of soil erosion and the measures taken in the United States, U.S.S.R., China, Australia and elsewhere to overcome it and to promote irrigation. He also mentions some of the improvements which could be made by the use of fertilizers, the control of plant diseases, the use of seeds of high-yielding strains, selective breeding and improved management of livestock.

The chapter on the international attempts which have been made to solve the world food problem is a very useful reference. This, told by one who has made his own outstanding and original contributions in this field, describes, in particular, the work of the League of Nations leading to the concept of "The marriage of health and agriculture", and of the Food and Agriculture Organization.

The British food position is treated in an appendix which underlines its insecurity and suggests that a committee might with advantage be set up to consider long-term problems of food in terms of agriculture, trade and finance rather than politics ". . . to ensure that, say twenty years hence, there will be sufficient food, either imported or home-produced, for the people of the United Kingdom".

The section which traces the accumulation of knowledge on human nutritional requirements contains one misleading statement. Having explained that it was originally thought that hard physical work requires extra protein for replacement of wear and tear of muscles, the author does not state that subsequent investigation has not supported this assumption.

One detects and regrets a certain nostalgia that it was not possible "to throttle down science after the First World War, and to give human society a chance to assimilate and adjust itself to the new forces", but applauds the conclusion that it is urgent for politicians of all countries to get together "to consider how they can evolve a world order suited to the new age of science".

PROGRESS IN ANTARCTICA

The Antarctic Today

A Mid-Century Survey by the New Zealand Antarctic Society. Edited by Frank A. Simpson. Pp. 389+45 plates. (Wellington: A. H. and A. W. Reed; London: Phoenix House, Ltd., 1952.) 47*s.* 6*d.* net.

THE establishment of the Falkland Islands Dependencies Survey in 1943, fifty years after the first known landing on the antarctic mainland, marks a turning-point in the history of human endeavour in high southern latitudes. Although Bruce established a weather station in the South Orkneys in 1903, and handed it over to Argentina for permanent occupation, the need for scientific stations on the continent itself was not generally appreciated until long afterwards. Since 1943, however, the example of the United Kingdom has been followed by other countries with antarctic territorial claims, and the New Zealand Antarctic Society has performed a useful service by directing attention to the significance of recent developments.

The book is divided into seven parts, with chapters by different contributors. Especially useful are those dealing with glaciology, geology and oceanography, and with marine resources. It is unfortunate that N. E. Odell, who provides an excellent summary of the glaciology of Antarctica, was unable to benefit from the results of the recent Norwegian–British–Swedish Antarctic Expedition. These do not confirm the evidence that he adduces to suggest that a marked recession of the ice sheet is in progress. The geology of Antarctica is described by Rhodes W. Fairbridge. Only about 0·2 per cent of the total land area of 5,000,000 square miles is geologically known; but Mr. Fairbridge has succeeded in making a commendable analysis of the structure of the continent. Although he does not make the point, more details of the mineral wealth are urgently required, for conflicting territorial claims are not likely to be settled while so much remains in doubt. The difficulties of mining in rock covered by ice up to 6,000 ft. thick are not necessarily insurmountable.

The greatest mainspring of human activity in the Antarctic is the exploitation of marine resources, and about one-third of the text is given to various aspects of this subject. There are comprehensive accounts by C. A. Fleming of the physical oceanography and by R. K. Dell of the marine biology of the Southern Ocean, and W. H. Dawbin ably describes antarctic whales and whaling. British and Norwegian achievements in the task of maintaining stocks of whales are recognized, but Mr. Dawbin should also have mentioned Japanese work.

As P. G. Law points out, valuable results in the physical sciences can only be expected from continuous observations over a long period. As yet this work has only just begun, but the papers by A. R. Martin on meteorology and by J. W. Beagley on ionospheric research leave the impression that many more antarctic stations must be established before the problems connected with weather and atmospheric physics in the southern hemisphere can be solved. The importance of ionospheric research lies in the fact that trans-antarctic aviation is not likely to materialize, even if weather stations and airstrips are available, until radio communications are more certain. On the other hand, the expense of such investigations, and the sparseness of the population of the southern, compared with that of the northern, hemisphere may retard the development of far southern air routes for many years.

It seems a pity that the book contains no concise history of exploration, which is dealt with partly in the introduction and partly in the final chapter. The chapters dealing with recent field-work, and especially that compiled by the editorial committee, are out of proportion, and it would have been better to draw all the information together in a single chapter. A few minor points deserve mention. Most of the contributions have lists of references, but those by R. A. Falla, describing antarctic birds, and I. L. Thomsen, concerning auroral studies, have not. The first navigator to sight the mainland was not Biscoe in 1831, but Bransfield in 1820, and the first known landing was made by Larsen in 1893, not by Bull and Borchgrevink in 1895. The Society has regrettably not conformed to the practice of giving place-names in the local official form, or at least of giving this form in brackets. But these are slight blemishes of a fine book, which deserves to be widely read.

J. D. M. Blyth

RECRUITMENT OF AMERICAN SCIENTISTS

Origins of American Scientists

A Study Made under the Direction of a Committee of the Faculty of Wesleyan University. By R. H. Knapp and H. B. Goodrich. Pp. xiv+450. (Chicago: University of Chicago Press; London: Cambridge University Press, 1952.) 56s. 6d. net.

Any problem arising in the United States concerning the origin of professional scientists is in some respects more troublesome than it would be in Britain, for whereas practically every student in Britain would enter an institution of 'similar' type offering up to a doctor's degree, an American student may commence his undergraduate work in a university or in a college (such as a liberal arts college) with no postgraduate degrees. In considering the need to increase the numbers of scientists, therefore, it may be necessary to determine what proportions of people have become scientists after commencing their studies in these different ways. Very broadly, reasons such as this stimulated the investigation which is described in this volume. The work was guided by a committee of the Faculty of Wesleyan University, with Prof. H. B. Goodrich as chairman.

One of the most serious difficulties that had to be faced was the selection of a suitable list or lists of scientists. Graduation was inadequate, for at that stage it may not be discernible what subsequent career is to be followed; this is much more likely to be true of American than of British students. After full consideration it was decided to use "American Men of Science", a publication which has now reached its eighth edition. It gives extensive lists of professional scientists, apparently showing some balance between the different sciences. There is, however, evidence to indicate that the methods of selection have tended to favour the inclusion of scientists in academic employment rather than those in industry, a discrimination which from the British point of view may reduce the value of much that follows. Taking this list, further reduced by selecting only scientists who hold the Ph.D. or equivalent degree (together with scientists who are 'starred' in that volume), some 16,000 were left. The college of origin was noted. The annual number of men graduates in science was obtained in all relevant institutions. Women graduates were ultimately omitted, partly because they form a limited part of the field, amounting to only around 2 per cent. Obviously a number of years must elapse between the date of first graduation and the completion of a research degree or the establishment of the individual as a professional scientist, and due allowance has been made for this lag. The investigation is therefore mainly historical, dealing with students who entered the university some time before the War; it does not purport to discuss conditions which would necessarily apply at the present time.

With these two values, the number of men science graduates and the related number of professional scientists, a basis of comparison (the productivity index) between different institutions is available. For example, listing the leading fifty institutions in the production of scientists, we find that the authors are able to include only five institutions at which there graduated annually, during the relevant period, more than two hundred, and of these two only could be called large universities. An interesting feature is the large number of liberal arts colleges in the fifty, devoted to fundamental scholarship rather than to specialized training. Only six are technological institutions. Nearly all the students of the latter concentrate on science, pure or applied; it is clear, however, that those who later follow a postgraduate course mostly do so in engineering, and if they undertake research in that field their interest is mainly technological and they have not been included in the list of scientists considered here. It may be noticed that a conspicuous position is occupied by the California Institute of Technology, which in many respects is different from other institutions specializing in technology.

The authors, it appears, have a chief interest in the education of 'pure' scientists, and this has to be remembered in reading all their conclusions. The British reader will learn a good deal about the smaller colleges. Several chapters are devoted particularly to small groups of colleges in which is given an account of the aims and achievements of individual institutions, of their history, and difficulties. For it is fully recognized that in their development they have been influenced by such factors as their geography, their finances, and their success or otherwise in obtaining men of the right type as teachers.

A. E. Trueman

Indian Epigraphy and South Indian Scripts

By C. Sivaramamurti. (Bulletin of the Madras Government Museum, New Series, General Section, Vol. 3, No. 4.) Pp. viii+280+133 text figures+12 plates. (Madras: Government Press, 1952.) Rs. 14-8-0.

THE author of this publication, who is already well known for his work on "Amaravati Sculptures in the Madras Government Museum" and as co-author of "Guide to Archæological Galleries" and "Illustrations of Indian Sculpture", is at present superintendent of the Archæological Section of the Indian Museum at Calcutta. His painstaking research in the field of epigraphy has been collected in the present volume.

The work is a valuable contribution to the study of Indian epigraphy, which is a necessary adjunct to the study of ancient Indian history, culture and ethnography. It is of special concern to those who are interested in the question of the evolution of the various Indian alphabets from a common source. The Indian subcontinent, with the possible exception of Kashmir and Assam, is generally deficient in an old historical literature. The innumerable inscriptions, copper plates and coins scattered all over the country partially fill this void. In his introductory chapter the author has discussed the value and need of studying this oft-neglected subject.

Mr. Sivaramamurti has drawn charts showing "the development of each individual letter of the Indian alphabet in different areas and during centuries in different types of script developed from the same parent stock" (p. viii), with emphasis on the development of the South Indian alphabet. He rightly remarks that "The scripts of South India have contributed enormously to the spread of Indian culture overseas" (p. 55). The truth of this statement is borne out by the conclusion which he has arrived at by the diligent comparative study of the epigraphy of those regions. He states: "The script of Ceylon is derived from Grantha Tāmil. The script of the inscriptions in Java like those of Pūrnavarman closely resembles the early script of South India. The same applies also to the characters used in the inscriptions of Annam or Campa" (p. 55).

In Plate I the author has placed the regional alphabets from various areas, including East Turkestan, Tibet, Ceylon, Burma, Annam, Malaya, Java and Borneo, side-by-side to facilitate a comparison of the individual characters. Here one misses the area comprising the north-eastern corner of India. Inclusion of scripts from inscriptions in Orissa, Bengal and Assam would have provided, in my opinion, a better perspective for a comparative study.

The author is to be congratulated on his valuable contribution to the study of Indian epigraphy.

M. C. GOSWAMI

Timber Progress and Desk Book for 1953

Edited by W. E. Bruce. Pp. 202. (London: Cleaver-Hume Press, Ltd., 1952.) 15s.

THE objective of "Timber Progress" is to record annually in authoritative, independent, easy-to-read articles the new ideas, new movements and latest achievements in the technology and commerce of the timber and allied industries. In a foreword David Irwin, chairman of the Education Standing Committee of the Timber Development Association, states that "this publication fills a long-felt want, containing as it does a series of articles by recognized authorities, a most comprehensive bibliography on timber literature and other useful reference items. It is a library in itself and will, I feel sure, be welcomed by student and employer alike".

Among the articles may be mentioned the following: some recent changes in timber trade practice; structures of new timbers; world review of the newer timbers and their commercial uses; moisture in wood and modern methods of seasoning; British-made plywood and its possibilities; development of modern furniture design in Britain; principles of conversion; and a reference section.

This little book furnishes evidence of the enormous increases in the imports of previously unknown timbers from tropical and sub-tropical forests. In connexion with South-East Asia, it is said that before the Second World War this part of the world provided certain specialized woods only, the most famous being the genuine Burmese teak which is to-day so scarce and expensive. In addition were imported some of the decorative woods such as satinwood, rosewood, pyinkado and gurjun. During the later years of the past century and the early years of the present one before the First World War, Indian forest officers made considerable efforts to place on the London or other British timber markets some of the fine species of Indian timbers, but they met with practically no success. The position of these tropical and sub-tropical timbers is very different nowadays. But much practical research has yet to be carried out before their utilization as a commercial proposition has been substantiated: the forests and their distribution in their habitat; the types of forests in which they are found, and in a mixed forest their proportion in the mixture per acre or hectare or square mile; and the accessibility for extraction at an economic cost. E. P. STEBBING

General Chemistry

An Elementary Survey emphasizing Industrial Applications of Fundamental Principles. By Prof. Horace G. Deming. Sixth edition. Pp. xii+662. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1952.) 46s. net.

THIS much-used text-book is an introduction to chemistry for university students including those not continuing its study. Prof. H. G. Deming presents the achievements of chemistry and its great economic possibilities not as attractions in themselves but as spurs to study a science worthy of, and requiring, considerable effort. His course follows no definite syllabus but covers approximately the requirements of the Intermediate B.Sc. of a British university, with some additions. These include a chapter on nuclear chemistry and four on organic chemistry, respectively, entitled as follows: hydrocarbons; alcohols, esters, carbohydrates; cellulose products and plastics; and elastomers, dyestuffs and medicinals.

Although Prof. Deming has the remarkable gift of finding simple explanations of difficult matters, his treatment is thorough. He expounds the physical basis of the chemistry in question, stresses the significance of structure and makes advantageous use of present-day knowledge and ideas. Besides the skilful expositions, the student is afforded an abundance of help by the interpolated questions, exercises, cross-references, informative illustrations and summaries for revision. Good as the earlier editions were, the present effort, the product of the author's ripe experience, is even better.

G. F.

Historical Aspects of Organic Evolution

By Dr. Philip G. Fothergill. Pp. xvii+427. (London: Hollis and Carter, Ltd., 1952.) 35s. net.

THE subject-matter of this book is exactly indicated by its title: it gives a historical account of the initial and changing conceptions of organic evolution from ancient times down to the present period of manifold observation and experimental investigation. There can be no doubt that this book will prove of interest and value to all who maintain either a general or a particular interest in scholarship germane to this major biological theme. The book is concisely comprehensive and, not least important, it is lucid and readable. In the first part the author traces the historical development of the idea of evolution, beginning in the remote and obscure Chinese, Babylonian and Egyptian periods, and culminating in the post-Darwinian period when evolution had become generally accepted as an established principle.

The second part deals with cytogenetics and modern causal theories of evolution. In this part, the rediscovery of Mendelism, chromosome studies and gene theory are considered. Finally, in the concluding chapters, there is a survey of the various recent theories of evolution, including neo-Lamarckism, neo-Darwinism and the views of particular exponents such as Lotsy, Willis and Goldschmidt. Various special subjects are dealt with in some eight appendixes. This book may be generally recommended as being likely to retain for many years to come its usefulness both as a valuable and readable text and as a work of reference.

Heat Transfer Phenomena

The Flow of Heat in Physical Systems. By Dr. R. C. L. Bosworth. Pp. xii+211. (Sydney: Associated General Publications Pty., Ltd.; London: Pergamon Press, Ltd.; New York: John Wiley and Sons, Inc., 1952.) 42s. net.

MOST books on heat transfer are written from the point of view of the engineer and contain relatively little discussion either of the nature of the underlying physical processes (for example, the mechanism of conduction) or of the relation of the subject to other branches of physics. Dr. R. C. L. Bosworth's survey is therefore particularly welcome because he lays especial emphasis on these aspects of heat transfer. Throughout the book he brings out the similarities and differences, quantitative as well as qualitative, between the transfer of heat, momentum, electricity, matter, etc. Particularly illuminating is the comparison between thermal radiation and conduction in gases with a long mean-free-path. The well-known 'electrical analogy' is considerably developed, and the existence of 'inductance' as well as 'capacitance' in thermal processes is pointed out.

In addition to tracing the main outlines of the subject in a concise manner, the book contains a good review of the most recent work on conduction, convection and radiation, including the technique of measurement, and gives extensive lists of references. Although some casual statements may be criticized—for example, that forced convection only outweighs natural convection when the flow is turbulent (p. 113)—and although misprints are rather unusually numerous, the book will be of lasting value to students and research workers. Only the purists among them will hesitate to accord full agreement to the publishers' prefatory claim that the book "satisfies a much needed want".

The Sky and Its Mysteries

By Ernest Agar Beet. Pp. 238+15 plates+56 figs. (London: G. Bell and Sons, Ltd., 1952.) 15s. net.

IN writing this book for the non-specialist, the author has preserved a sense of balance by devoting by far the greater portion to the solar system, a description of some of the more important instruments used by the astronomer, and a short historical sketch up to about the end of the past century. Mathematical treatment of the subject has been almost entirely eliminated, which will enhance its interest and value for many beginners; while there is little new in the text, the manner of presentation is very lucid, and it is certain that the book will make a strong appeal to many amateur astronomers. The map at the end may seem a weak point in the work; but, as the author points out in the preface, "it is to supplement, not to replace, the normal kind of star map for outdoor use". A list of periodicals supplying information on the night sky, month by month, is given on p. 229, one an American publication and three British; but it might be suggested that some additional British publications should be referred to in a future edition—especially those which describe the times of the rising and setting of the planets. A few points require slight amendments in the revision as, for example, the statement on p. 121 that Mars is at its nearest when fully illuminated, and that on p. 138 regarding the sporadic meteors with hyperbolic velocities, and some others; but these are very minor points which do not detract from the value of this excellent book. M. D.

Puffins

By R. M. Lockley. Pp. xi+186+17 plates. (London: J. M. Dent and Sons, Ltd., 1953.) 18s. net.

MR. R. M. LOCKLEY has added an interesting volume to the fast growing list of bird monographs. His long residence on the island of Skokholm and his intimate acquaintance with the large puffin population of the Pembrokeshire islands qualifies him for the task of writing on *Fratercula arctica*. He does so both informatively and entertainingly, most of what he tells us being the result of long periods of puffin-watching on the islands of Skokholm and Skomer, particularly the latter, where he estimates at least 50,000 pairs bred in 1952. His book deals with the puffin from the time it returns to its breeding haunts in early spring until the last deserted young one goes off to sea. In addition, the author has chapters on the "Mind of a Bird", the "Winter Ocean" and "Man and Puffin", with appendixes on "Numbers", "Distribution", "Recoveries of Ringed Puffins", etc. Under the heading of "Numbers" he tries to estimate the total population of *Fratercula arctica* and thinks it may be (including the sub-species *F. a. naumanni* of Spitsbergen, *A. a. arctica* of north Norway, Iceland and North America, plus *A. a. grabae* of Britain, the Faroes and France) between fifteen and sixteen millions of birds. But he adds a word of warning, saying it is "clear that the present figure is a reduction, probably a considerable one, on the population of one hundred years ago". However, he concludes by saying that, "still the puffin remains one of, if not the, most numerous of seabirds in the whole Atlantic".

FRANCES PITT

RELATION OF RELIGION AND SCIENCE

By the VERY REV. W. R. MATTHEWS, K.C.V.O.
Dean of St. Paul's Cathedral

THE problem of the relation of religion and science is not dead, as we are often told, but has been made obscure because it has become difficult to define the issue clearly. In the days of T. H. Huxley and Gladstone it was comparatively simple. The Christian religion asserted a great number of propositions which it held to be true, while science, or scientific researchers, had come to conclusions which seemed, in many cases, to be irreconcilable with those propositions. Now, however, the epistemologists have raised the question of the nature of scientific 'truth' and the still more devastating question whether religious propositions have any meaning and can be described as either true or false. The consequence is that discussions of religion and science tend to degenerate into a kind of shadow boxing: neither side of the argument really comes to grips with the other. Yet the 'plain man' feels that there is a problem and a vital one. In his simple way, he would say that the kind of universe which science progressively discloses is singularly unlike the kind of universe which is presented by the documents and the doctrines of the Christian faith.

It is one of the many merits of Prof. Coulson's recent book that he is quite clear on what he is talking about[*]. By science he means the results, up to date, of the application of the scientific method in every sphere where it has been applied and the method itself; by religion he means the Christian religion, not as a vague sentiment or an admiration for the character of Jesus, but as a system of doctrine and worship. Nor is there any doubt about the purpose of his inquiry. It is, "To see whether there is any coherence between science and religion, and whether, in an age of science, it is possible to hold the faith with propriety and with intellectual integrity".

This little book, consisting of three lectures given under the Riddell Memorial foundation, contains more sound sense on the subject than most works five times its size, for it deals with the ultimate issues and keeps to the point. The challenge of the two universes and two systems of knowledge—the scientific and the religious—is always before his mind. He rejects any theory which would vindicate religion by somehow inserting it into the scientific universe, finding a place for it either in the yet unexplored territory or in the incoherences which can be discovered in scientific conclusions. Perhaps he is a little too hard on theologians who find something of interest to them in Heisenberg's uncertainty principle, for if determinism breaks down in one part of Nature, it may well be only an appearance, or a useful fiction, elsewhere; but undoubtedly he is splendidly right when he says, "If God is here at all, it must be at the beginning of science and right through it".

The concept of Nature inevitably comes up for discussion. Prof. Coulson rejects the idea that Nature is 'given', in the sense that it lies 'out there' presenting us with a puzzle to be solved. In a very general way one may agree that his view of Nature is Kantean. Certainly he holds that, in a sense, "mind makes nature", and that it is totally misleading to assume that we have any knowledge of Nature, or of the existence of Nature, apart from our minds. In some of his phrases he seems to go beyond Kant and to verge on Berkeleyan idealism; but on the whole, he holds fast to the conviction that, though in one sense "the whole scientific universe is a construction of our own", in another sense, it has objective validity, though it is not easy to gather from these lectures precisely what this latter sense can be. But, after all, Kant himself left us in the dark about the "things in themselves".

The short answer to the question, why there can be two different views of the universe, the religious and the scientific, both well-founded, is that they are two distinct views of the same object. This thought is developed with great skill by means of an analogy—that of the different aspects of Ben Nevis. This might easily have been too facile a solution; but Prof. Coulson is careful to point out where his analogy fails, and perhaps the reader would be well advised, in reflecting upon this conception of two points of view, to bear in mind the important passage at the end of Lecture 1, where it is argued that Nature and man are indissoluble and that Nature has a spiritual meaning. In this connexion the author has a word for theologians as well as for scientists. Too often, he thinks, theologians regard Nature as merely the stage on which the great drama is performed, whereas they ought to think of it as a part of the play.

One difficulty may be mentioned about the 'aspect' or 'point of view' theory. It would certainly be more convincing if there were only one religion; but the great religions of the world differ in a marked degree from one another in their conceptions of the universe, of the ultimate Reality and of man's place in the whole, yet presumably both the Buddhist and the Christian systems arise from the religious apprehension of the One Object. Two possible answers suggest themselves to this objection. It might be maintained that there is, in fact, a fundamental agreement beneath the differences of the great religions, and it might be argued too that there is, in fact, no settled scientific view of Nature. In both spheres, so to speak, there are shifts of focus.

It is not possible to touch upon all the lines of thought which are opened up by this suggestive book; but we must not omit one which evidently is very near Prof. Coulson's heart, the 'message' which he would give to theologians and scientists alike. It is that we should enlarge our idea of the life of the Spirit. The work of scientific research, when faithfully done, is a spiritual activity and a service of God. All the disciplines which constitute culture are, in essence, spiritual, and each needs all the others. The ideal of the Christian Church is a fellowship of all who 'wonder'—the scientist, the historian, the poet and artist, the philosopher and theologian, and also the unlearned man of faith. In this fellowship "the fullness of each separate discipline is revealed". In such words we welcome the authentic voice of Christian humanism.

THE ITALIAN NATIONAL SCIENCE MUSEUM AT MILAN

By W. T. O'DEA
Science Museum, London

THE museums of Italy are at a most lively stage of development. During the War they suffered heavy damage; but rebuilding has proceeded at a pace that makes progress in Britain seem very inadequate by comparison. The result of rebuilding, re-design and re-organization has been a sharp rise in attendances from 800,000 in 1946 to 4,725,000 in 1952 at national museums. This figure is nearly double the highest pre-war number of visitors in a year (1937) and applies, naturally, to art museums in the main. There is, however, one striking example of the way science has shared and is to share in these developments.

The National Museum of Science and Technology at Milan is housed in buildings which follow the plan of the badly war-damaged early sixteenth-century Monastery of San Vittore. Leonardo's "Last Supper" was painted a few years earlier only a short distance away and he was still working in Milan when the Monastery was built. The man who, above all others, combined mastery in sciences with mastery in the arts is therefore specially honoured in this new Museum. The display of models to celebrate the fifth centenary of the birth of Leonardo da Vinci has already been described and most of the models are replicas of those built in Italy, exhibited there in 1939, taken to New York in 1940, and destroyed by fire in Tokyo during the War. It will therefore suffice to say that these models are built with a genuine feeling for the methods and materials of the time, are very well set out, and are to such well-chosen sizes that the aeronautical items, for example, really do look as though they might take to the air without breaking up. Leonardo's sketches were not dimensioned, so that interpretation becomes most important when building models to his ideas. In a few cases, such as excavators and cranes, Leonardo's original suggestions are shown in model form with models beside them to show the not so very dissimilar (making allowances for a five-century interval) modern counterparts.

So far the Museum is in a very early stage of development, although representatives at the third International Conference on Museums held in Milan this year were greatly impressed with what had been done, so quickly, under the guidance of Dr. Guido Ucelli. The Leonardo exhibits predominate, with another important gallery displaying an attractive collection of models of warships, merchantmen and small craft as the Italian Naval Museum. A start has been made on a section to illustrate the history of aeronautics; but this can scarcely be more than a token until a new arch-roofed building, the frame and most of the walls of which are now to be seen, is completed. Here the aeronautical collections of the Italian Army, at present stored in Rome, are to be set out by Captain Soldatini, who has already been responsible for the instruments of warfare in the Leonardo Collections.

Extensions are also being built at the present time to include a cinema for scientific films and a library of the history of science, to which Dr. Ucelli will contribute his own extensive collection of books. There already exists a reading room in which many technical periodicals are regularly received.

At the present time about two thousand visitors go to this new Museum every week; but it is to be expected that much greater numbers will attend as the collections develop. The support of industry has still to be obtained before many projected new sections can be planned on an adequate scale. There is little doubt that this will be forthcoming eventually, and in that respect the wisdom of actually opening the Museum to the public is incontestable. Ships, aeroplanes and Leonardo da Vinci happened to be the three subjects on which sufficient material or impetus existed. For future developments much will depend upon which industries react most favourably to the suggestion that they should contribute both in material and in finance for display. The fact that there are now an embryo but effective Museum and already an interested public should be of the greatest assistance in influencing such potential benefactors.

The Museum buildings themselves are worthy of comment. The damage to the sixteenth-century Monastery (itself on the site of an older monastery, which in turn occupied a site on which there can still be seen remains of a Roman wall) was of so fundamental an order that the present buildings may practically be described as new. Such skilful use has been made of new materials that the monastic atmosphere remains; and yet an impression of modernity is conveyed at the same time. The Leonardo Gallery on the first floor has a high arched roof and looks, from its length, not unlike a cloister in some respects. Yet the display of Leonardo models is modern and attractive. Each model is on a table made by bending and toughening a long

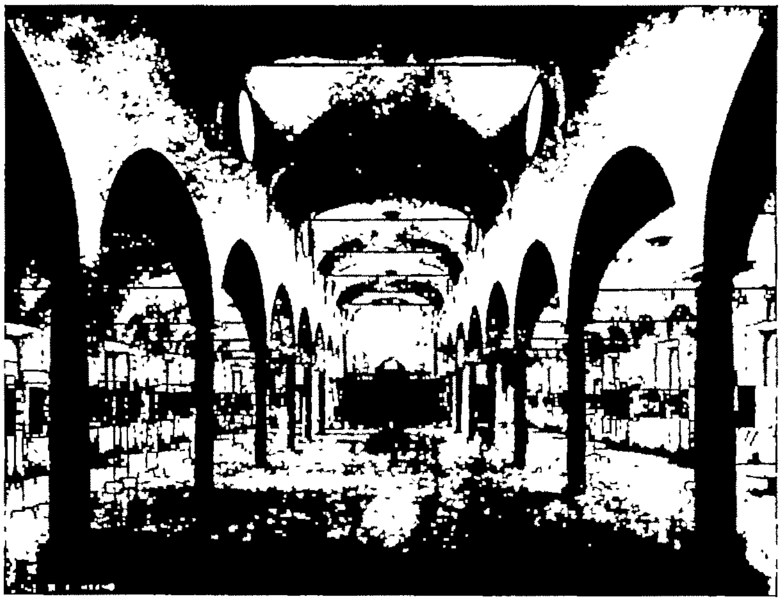

Fig. 1. View of the large conference hall where the display from the International Conference on Museums is arranged

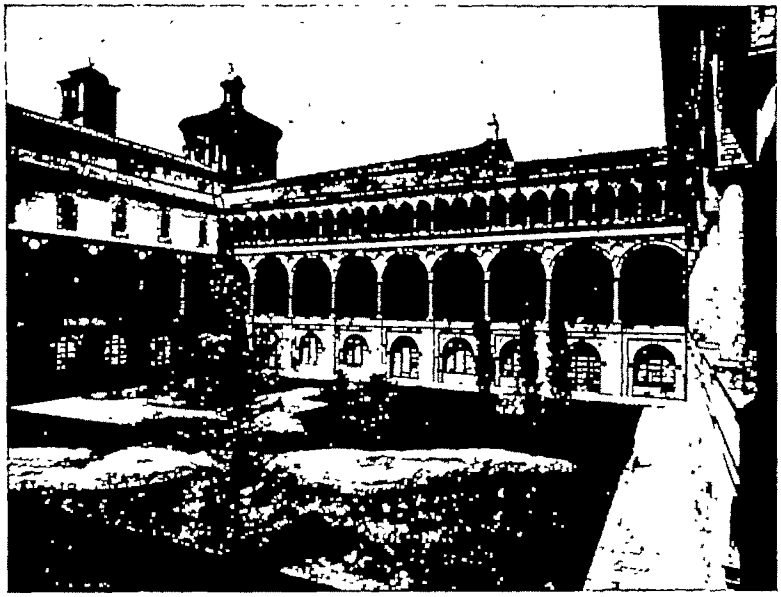

Fig. 2. View of the first cloister. Foreground: remains of ancient Roman walls

rectangular sheet of plate glass. A concealed fluorescent lamp lights each model and the only daylight comes from a few small circular windows up near the ceiling. The finish of walls and ceiling is of whitewash. The result is a well-graded illumination and no violent contrasts to disquiet the eye such as the transition from, say, 10 candles/sq. ft. on an exhibit to a brightness of 2,000 candles/sq. ft. or more from the sky seen through a window as soon as the eye is lifted. Unrestful contrasts of this order are common in most museums, and it is very pleasant to go around galleries such as these in Milan where violent brightness transitions are avoided.

This Science Museum in the making is worthy of great support, and its development should be very interesting to watch. In connexion with the International Conference on Museums a series of more than a hundred panels of photographs were contributed by more than twenty museums of science and technology throughout the world to illustrate their techniques and achievements. These are displayed around the principal lecture theatre in the Museum, and Dr. Ucelli hopes to retain them for some time to help him to show what other countries are doing and to obtain further interest in his own plans. In these he will have the best wishes of everybody in the museum world and should attract the support of both science and industry.

SIZE EFFECTS IN THE INITIATION AND GROWTH OF EXPLOSION

By Dr F. P. BOWDEN, F.R.S., and K. SINGH

Research Laboratory for the Physics and Chemistry of Surfaces, Department of Physical Chemistry, Cambridge

THERE is a good deal of evidence that the initiation of explosion by impact and by friction is, commonly, thermal in origin[1]. The mechanical energy of the blow or of rubbing is degraded into heat and concentrated to form a small 'hot spot'. These hot spots, though small, are large compared with molecular dimensions. Their size, as we should expect, is very dependent upon the experimental conditions; but they may range from c. 10^{-5} to 10^{-3} cm. in diameter, and their duration[2] may be short, for example, 10^{-5} sec. With many explosions the necessary hot-spot temperature may be c. 400° C.–500° C. These hot spots are readily formed in two main ways: (1) by the adiabatic compression of small included gas bubbles; the presence even of a single tiny bubble can render most explosives extremely sensitive to impact; (2) by friction on the confining surfaces, on grit particles or on crystals of the explosive itself. Under very extreme conditions, a sufficient rise of temperature can be produced by a viscous heating of the rapidly flowing explosive, but this normally requires a very high impact-energy.

On this thermal mechanism, we should expect that the growth of a small explosion from a hot spot to one of finite dimensions would be governed by simple physical considerations. If the rate of evolution of heat by chemical reaction within the small volume is greater than the rate at which it is lost to the surroundings by conduction and other means, it will grow; if not, it will die away. The general treatment of this has been given by a number of workers[3]. Calculations for some solid and liquid high explosives[4] show that for a hot-spot temperature of 400°–500° C. the minimum size is in the range 10^{-3} to 10^{-5} cm. diameter. This is in agreement with our measured values.

Irradiation with Electrons and Neutrons

We have recently made some further studies of hot-spot size in initiating explosives by irradiating the explosive crystals with beams of electrons and neutrons, and also by heating very small crystals. It has been suggested[5] that the simultaneous decomposition of two adjacent molecules of lead azide could lead to explosion. Kallmann and Schrankler[6] have observed the initiation of T.N.T., mercury fulminate and azides when bombarded with an intense beam of hydrogen, argon and mercury ions. They have suggested that the explosion is due to the activation of a few neighbouring molecules. Muraour[7] has also observed the explosion of silver acetylide when irradiated with high-speed electrons, and explained the result in a similar way. We find that when crystals of lead azide are irradiated with an electron beam of 75 KeV. and 200 μamp., explosion occurs. It was thought, however, that this and the explosion reported by other workers might be due to a bulk heating of the explosive. The explosive was, therefore, replaced by crystals of potassium nitrate (melting point, 334° C.). These were readily melted in the electron beam, showing that the temperature rise was greater than 334° C. This and additional experiments on the fusion of metallic wires provide strong evidence that the explosion of the azide under these conditions can be due to bulk heating.

In order to avoid this bulk heating, the explosive crystals were bombarded with slow neutrons (flux, 10^8 neutrons per cm.^{2} per sec.). The experiments

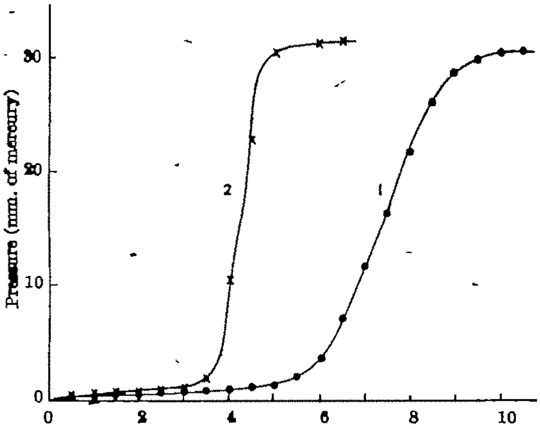

Fig. 1. Influence of neutron irradiation on thermal decomposition of lithium azide: (1) unirradiated; (2) after irradiation. Temperature, 250° C.; pressure, 10 cm. mercury

were carried out with cadmium azide, lead azide, silver azide, silver acetylide and lithium azide. In no case did explosion occur, although interesting changes were observed in the crystals. In a second series of experiments, the crystals of lead azide and cadmium azide were mixed with uranium oxide and irradiated with neutrons so that fission of uranium-235 took place. Again no explosion occurred. In these last experiments, the energy of the fission products is c. 94 MeV. and the range of these particles in lead azide is c. 10^{-3} cm. It is clear that irradiation of this kind could produce the decomposition of a large number of adjacent azide molecules, but it does not cause explosion.

If we assume that the energy is dissipated along the track of the particle to form a 'hot cylinder' equal to its length, and of a temperature of 400° C., the diameter of this cylinder would be about 2×10^{-6} cm. This did not cause explosion even when the crystals were maintained at 290° C. during irradiation. Irradiation with α-particles and γ-radiation also failed to cause explosion.

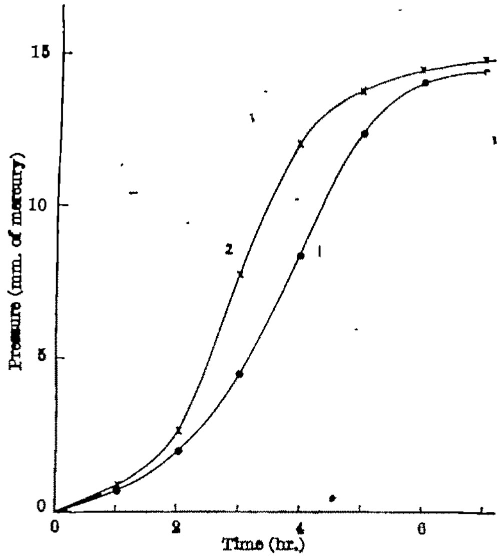

Fig. 2. Influence of neutron irradiation on thermal decomposition of lead azide; (1) unirradiated; (2) after irradiation. Temperature, 281° C.

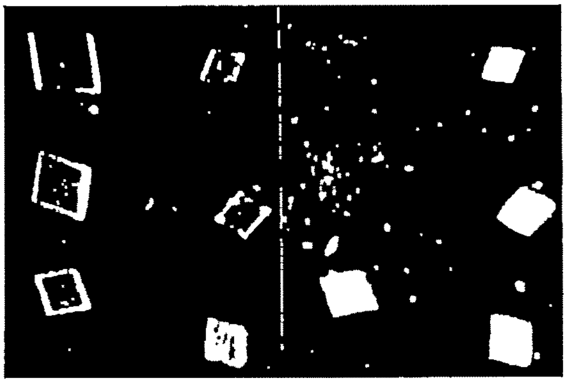

Fig. 3. Influence of crystal size on explosion. Cadmium azide (a) before heating, (b) after heating at 320° C. for three minutes. The largest two crystals have exploded, the smaller ones decompose slowly

The only exception we have so far observed is nitrogen iodide, which does explode when irradiated by neutrons. However, Meldrum[8] has shown that nitrogen iodide will explode at room temperature if ammonia is removed from the surface.

Although neutron irradiation under these conditions does not, in general, cause explosion, it does produce interesting changes in the crystal. Colour changes and darkening, indicating the formation of *F* centres and nuclei, are observed. This affects the subsequent course of the thermal decomposition of the explosive. This is illustrated in Figs. 1 and 2. With lithium azide, the induction period is reduced to about one-half and the rate of decomposition is considerably increased. With lead azide the thermal decomposition is also accelerated.

Influence of Crystal Size

If azide crystals of different sizes are arranged on a glass plate and placed in a furnace at a fixed temperature, it is found that crystals above a certain size explode, whereas those below the critical size decompose slowly. This is illustrated for cadmium azide in Figs. 3*a* and 3*b*. The critical size appears to be determined by the smallest dimension of the crystal; for example, its thickness if it has a plate-like structure. The critical size is dependent upon temperature, and some typical values for cadmium azide are given.

Temperature (°C.)	Critical size
320	24×10^{-4} cm.
325	20×10^{-4} cm.
330	17×10^{-4} cm.

It is interesting to see that this critical size, of a few microns, is similar to the hot-spot size measured in other ways. Analogous effects were observed with crystals of α-lead azide and silver azide. If the crystals are below the critical size, or if larger crystals are heated at a lower temperature so that only thermal decomposition takes place, the crystals split and break up along crystallographic planes. This is illustrated in Fig. 4*a* for cadmium azide and in Fig. 4*b* for α-lead azide. This suggests that the rate of decomposition may be a maximum along preferred planes within the crystal. The decomposition involves the formation of metallic nuclei and the evolution of gaseous nitrogen, accompanied by a large amount of heat, and this may easily lead to a splitting of the crystal. This splitting can occur with violence. The spreading of the dislocations and cracks through the crystal may play a part in the propagation process.

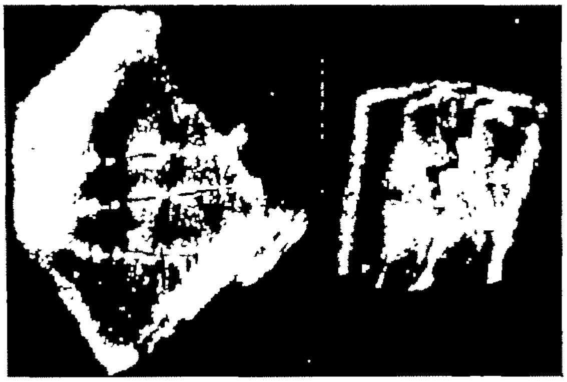

Fig. 4. Crystals of cadmium azide (*a*), and α-lead azide (*b*), which are decomposing thermally. Note cracking and splitting along crystal axes

It will also influence the rate of thermal decomposition by exposing a large amount of fresh surface.

Crystal Size and Impact Sensitivity

(with A. M. Yuill)

From similar considerations we may expect that the impact sensitivity of a crystal will be dependent upon its size. If the crystal is too small, the reaction will not be able to grow to explosion and the initiation will then, apparently, be unsuccessful. Mr. A. M. Yuill has investigated the effect of crystal size on the impact sensitivity of lead azide. Single crystals of the azide were placed on an anvil and struck with a flat-faced hammer, using an apparatus described elsewhere. The results are illustrated in Fig. 5.

Curve 1 is for individual crystals, and it will be seen that below a certain size the impact sensitivity is very dependent upon the size of crystal. For a crystal of 8×10^{-2} cm. in size, the impact energy for a 50 per cent probability of explosion is c. 5 kgm.cm.; as the crystal size is decreased, the necessary impact energy increases, and with a crystal of about 1×10^{-2} cm. it has risen to 200 kgm.cm. If, however, a heap of crystals of uniform size is used (curve 2) the impact sensitivity is independent of the size of the individual crystals in the heap and remains approximately constant at 2 kgm.cm. over this size-range. There may be two factors involved. First, the probability of explosion is determined by the number of potential initiation centres or hot spots, and this is naturally greater for large individual crystals than for smaller ones. The second is the effect discussed above: the reaction cannot grow to explosion unless the crystal exceeds a critical size. This critical size is dependent upon the initial hot-spot temperature and hence upon the impact energy. It should be noted that, under impact, the single crystals are crushed and flow plastically to form a pellet the thickness of which is about one-tenth to one-quarter that of the original crystal. If, therefore, the explosion starts at a late stage of the impact, it may be this thickness which is the limiting factor.

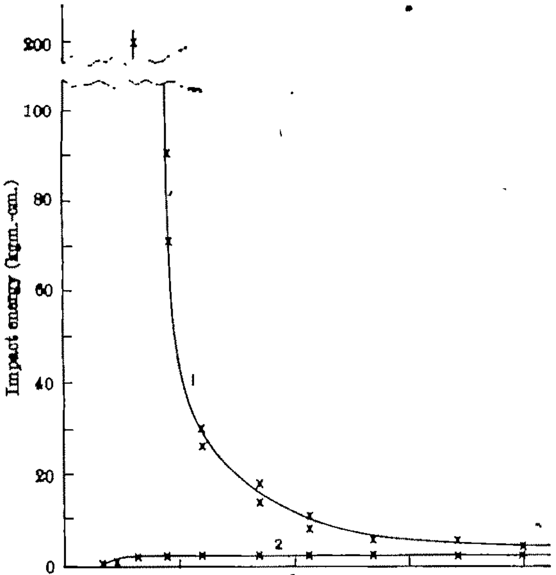

Fig. 5. Influence of crystal size on the impact sensitivity of lead azide; (1) single crystals; (2) heap of crystals

These experiments provide strong evidence that the explosion nucleus must exceed a critical size (which is quite large and is determined primarily by thermal considerations) before it can grow to detonation. Earlier work[1] has shown that, in addition to being a precarious process, the growth can be complex. For many explosives it begins as a comparatively gentle burning which accelerates to a few hundred metres a second before passing over into detonation, and the successful growth of the explosion requires critical conditions. The propagation of the low-velocity detonation is itself assisted by air bubbles and other sources of local hot spots[9]. The chemical reactions occurring during this burning phase are different from, and less complete than, the decomposition in detonation[10]. With metallic azides this intermediate burning stage is not observed. Very frequently, in sensitivity tests and in practical operation, the failure of an explosion to take place is due, not to a failure in initiating the reaction, but simply to a failure in the growth process.

WILHELM OSTWALD (1853–1932)

By Prof. J. R. PARTINGTON, M.B.E.

SEPTEMBER 2 is the centenary of the birth of Wilhelm Ostwald (1853–1932), one of the most influential physical chemists of the second half of the nineteenth century. His own investigations of chemical equilibrium convinced him of the importance of the general law of mass action proposed by Guldberg and Waage in 1867, and from 1887 he welcomed the new theories of solution of van't Hoff, of electrolytic dissociation of Arrhenius, and of galvanic cells of Nernst. Ostwald introduced chemists to the use of thermodynamics (which he tried to simplify in his system of 'energetics'), and was the first to emphasize the importance of the little-known publications of Gibbs and the value of the phase rule. These aspects of physical chemistry led him to under-estimate the importance of the atomic theory, but he recognized its significance after the work of Perrin on fine suspensions, and the discovery of radioactivity, had given it what he regarded as an experimental foundation. His own work on catalysis had led him to formulate the main features of the phenomenon in a manner which emphasized the observed facts and minimized the unverified (or unverifiable) and unnecessary hypothetical interpretation of them. This method of approach was typical of his outlook.

In his time, Ostwald was an international authority and his influence was comparable with that of Berzelius in an earlier generation. Many chemists, before adopting or using new theories, waited first to see what Ostwald would say about them and to what form he would reshape them to suit chemical requirements. His books, especially the smaller "Outlines of General Chemistry" and its many translations, were a powerful stimulus to the study of the newer physical chemistry, and his influence can be traced to-day in many directions, although its origin may not be adequately recognized. He was pre-eminently a clarifier and systematizer of knowledge, and an indefatigable defender and exponent of the newer physical chemistry based on the theories of solutions and electrolytic dissociation. His insistence that physical chemistry is a study equal in rank to any other branch of chemistry was necessary and important. Whole branches of chemistry now taught as commonplaces won their way into the science only after prolonged battles against either determined opposition or studied indifference. In maintaining their claims, Ostwald was much to the fore.

Ostwald was a man of many interests, in literature, music and art as well as in science. He devoted much time to the development of a colour scale and of an international language. He was greatly interested in the history of science and founded the "Klassiker" series. He believed that a historical approach had a disciplinary value. His many pupils venerated him and his influence in physical chemistry was fruitful and beneficial in many ways. It can be said with truth that physical chemistry owes very much, both directly and indirectly, to the research and teaching of Ostwald.

OBITUARY

Prof. F. H. Rein

THE death of Prof. F. H. Rein occurred at the age of fifty-six on May 14, at Göttingen, where he had occupied the chair of physiology from 1931 until 1953. He had recently resigned on his appointment as director of the Max-Planck Institute for Medical Research in Heidelberg, but had not actually taken up his new post.

Rein's scientific work consisted mainly in the application of ingenious physical and mechanical principles to physiological problems, and among the results of this work were the 'Thermostromuhr' and the 'Stoffwechselschreiber'. The 'Thermostromuhr' has since been criticized, and certain of its limitations have been shown; but in Rein's hands it made possible the investigation of many problems of the circulation as shown by the long series of publications from his Institute. It was a tragedy that Rein reached the peak of his ability when the position in Germany was becoming unfavourable for scientific work, and when international scientific relations were becoming difficult and finally impossible. When he gave a series of lectures in London in 1937 on the relation between metabolism and blood flow, he greatly appreciated the contact with English workers and was deeply concerned with the increasing difficulty of getting more interchange between Great Britain and Germany. The complete separation of the two countries during 1939–45 was followed by a great increase in the growing tendency in Britain to look to the United States rather than to the Continent for scientific exchange. This combination of circumstances has made Rein's work less widely known and appreciated in Britain. In addition to his numerous original papers he wrote a "Text Book of Physiology" which reached ten editions and is widely used in Germany. He was also senior author of the Physiology Section of the Fiat Reviews of German Science during 1939–46.

In his private life Rein was undemonstrative and somewhat reserved; but he inspired an intense loyalty in his younger colleagues, a number of whom now occupy chairs of physiology in Germany and elsewhere. Beneath his reserve he was extremely friendly, and he and his wife entertained the workers and visitors at his Institute with a kindly hospitality. His services to the University at Göttingen were great. He was responsible for the new Institute of Physiology which was completed in 1938. After the War he acted as rector of the University at a very difficult period, and he did much for the rehabilitation of the University. He was also one of the founders of the Fridtjof Nansen House in Göttingen, which was a centre for international student activities.

NEWS and VIEWS

Royal Aeronautical Society: Medal Awards

THE following Medals have been awarded by the Royal Aeronautical Society and will be presented at a meeting at the Royal Institution, London, on September 14: *Society's Gold Medal*, which is the highest honour that the Society can confer, to Mr. E. F. Relf, for his outstanding contribution to aeronautical science over a period of many years; *Society's Silver Medal*, to Mr. H. Grinsted, for his outstanding work in aeronautical engineering; *Society's Bronze Medal*, to Mr. L. Boddington, for his work on the development of naval aircraft; *British Gold Medal for Aeronautics*, to Mr. R. E. Bishop, for his outstanding contribution to aircraft design; *British Silver Medal for Aeronautics*, to Mr. J. E. Gordon, for his excellent work in the sphere of aircraft structural plastics; *Wakefield Gold Medal*, to Mr. F. W. Meredith, for his work in the design of automatic pilots and aircraft instruments; *Simms Gold Medal*, to Major P. L. Teed, for his paper on "Fatigue of Aircraft Materials with Special Reference to Micro-Structure"; *George Taylor (of Australia) Gold Medal*, to Group Captain E. A. Whitely, for his paper on "The Spacing of Aircraft under High Density Approach Conditions".

Commercial Solvents Award in Antibiotics

Drs. Ibert C. Wells (Syracuse, N.Y.), Edwin E. Hays (Chicago, Ill.), E. A. Doisy (St. Louis, Mo.), and William L. Gaby (Philadelphia, Pa.) have been awarded the 1952 Commercial Solvents Award in Antibiotics for work on antibiotics from *Pseudomonas aeruginosa*. These workers have demonstrated that, in addition to pyocyanine, *Pseudomonas aeruginosa* produces several other antibacterial agents; they have worked out methods of isolation, separation and purification of these agents, defined their physical and chemical properties, proposed structural formulæ for them and, by degradation and synthesis, proved the acceptability of the proposed formulæ. The Commercial Solvents Antibiotics Award was established in 1950 and is administered by the Society of American Bacteriologists. It consists of a gold medal and 1,000 dollars, and is awarded to any person or group of persons working in the western hemisphere who have made an outstanding contribution in the field of antibiotics during the past year.

Links between School and University

Believing that the latter years of a pupil's time at school and the years at a university should be as closely integrated as possible, the Council and Senate of the University of Leeds are building up the closest possible links with schools. Last year, for example, two booklets were prepared describing the courses available in science and technology. These booklets are intended to help careers masters and others to advise school boys and girls in their latter years about university courses that will best qualify them for the careers of their choice. The University has also become aware that it must devote close attention each year to the selection of new students of the right academic standards to keep the size of the University about constant. In the annual report for 1951–52, the vice-chancellor, Sir Charles Morris, suggests that this is most likely to be achieved by making a selection from among the applicants as early as possible. The fact that most candidates still apply to several universities and university colleges is the cause of much wasted effort and of much disappointment; it would appear that joint action by universities and university colleges in this matter is both desirable and necessary. To some extent the problem of selection has been made more difficult by the change from School Certificate and Higher School Certificate examinations to the General Certificate of Education examinations. On the other hand, headmasters and headmistresses are giving most helpful confidential reports, and heads of university departments have been able, to a much larger extent than hitherto, to interview applicants for admission and make a personal assessment of promise and suitability.

Use of Antibiotics in Agriculture

Two pamphlets, Statutory Instruments Nos. 1172 and 1174, 1953 (London: H.M.S.O.; 2*d*. each), have recently been issued by the Ministry of Health in connexion with the use of aureomycin and penicillin; the regulations come into operation on September 1, 1953. Aureomycin, which is intended for parenteral injection, is added to substances coming under control of the Therapeutic Substances Act, 1925 (M.H. 220). At the same time, both penicillin and aureomycin, which by the Penicillin Act, 1947, cannot be used except under the direction of doctors, dentists and veterinary surgeons, are now allowed to be incorporated in pig and poultry food with certain safeguards (M.H. 246). Medical supplies of these substances will not be affected. A recent report by the Agricultural Research Council (A.R.C. Report No. 13) has shown that the addition of these substances to pig food increased the live weight gain from 10 to 14 per cent and improved the efficiency of food conversion by 6–7 per cent without affecting carcass quality.

Nigerian Forest Administration: Annual Report for 1950–51

The annual report for the year 1950–51 of the Nigerian Forest Administration (pp. 64. Lagos: Govt. Printer; London: Crown Agents, 1952; 9*d*. net) provides food for reflexion and some uneasiness. After fifty years of a forest service in the country it is difficult to see that a sound basis of administration from the forestry point of view has been brought into force. The approach to forest conservation, instead of being made to the native chiefs by the administration service, was left to the forest officer, who possessed no administrative jurisdiction in the district except over the forest reserves. Consequently, in the south, where the heavy timber forests exist, the area reserved is said to be inadequate for a growing population. The big timber forests were expected to be a source of revenue to the country and the Forest Department was to obtain this revenue. It seems to have been overlooked that, in the past, the first call on the forests in a tropical and sub-tropical country is the provision of the requirements in small materials of the local agricultural population, and, secondly, or of equal importance, the maintenance of forests on the catchments of rivers and streams. For this purpose the government of the country requires to have at its elbow a senior forest expert who can advise on and guide the general forest policy and see that it is carried out throughout the several parts of the country. From the present report it appears that the Nigerian Forest Department is to be split up into three regional units each with its own chief conservator, the whole being loosely knit under the influence, but not command, of an inspector-general of forests—a most ambiguous expression, so far as his responsibilities are concerned. Africanization of the Department is proceeding apace, and it is difficult to visualize the kind of forest administration and management which the British forest officers will apparently be handing over in due course to their African successors.

Sheffield Organization for the Interchange of Technical Publications

The twentieth annual meeting of the Organization for the Interchange of Technical Publications in Sheffield and District was held recently in the Central Library, Sheffield. The admission of the British Iron and Steel Research Association brought the total membership up to forty, including industrial establishments fifteen miles distant from the city. During the year 1,937 publications were interchanged, this being a record total. The meeting considered the difficulties caused by the lack of current indexes of Patent Office publications and urged the issue of weekly alphabetical name indexes in the official *Journal*, with quarterly and annual cumulations. A complete revision of the union list of periodicals and their files available in the libraries of members was also recommended. It was reported that the City Science and Commerce Library had been made a deposit library for the reports of the British Atomic Energy Research Establishment; the reports of the United States Atomic Energy Commission are already held in the library. All these reports are available for loan outside the area on payment of postage. The members of the Organization agreed to co-operate in the production and issue of additions to the "Research Bibliographies" prepared by the City Science and Commerce Library, the sixty-first of which, "Shell Moulding Practice (Croning or 'C' Process)", has been in heavy demand from many parts of the world.

Recording Photoelectric Photometer at Kodaikanal Observatory

There are certain inherent disadvantages in using photographic photometry in the study of profiles of Fraunhofer lines, and workers in this field have felt the need for a spectrophotometric technique independent of the photographic process. When Brück was at Cambridge some years ago, he devised a photoelectric spectrophotometer using a vacuum photo-cell in conjunction with an electrometer triode; a recording photoelectric spectrophotometer has been built at the Kodaikanal Observatory on essentially similar lines and is described in a paper by A. K. Das, R. Ananthakrishnan and B. N. Bhargava, recently reprinted from the *Indian Journal of Meteorology and Geophysics* (2, No. 2; April 1951). The spectrum is provided by a high-dispersion prism spectrograph—a seven-prism instrument with a focal length of about 21 ft., giving a dispersion of 2·4 A. per mm. in the region of the *D* lines. The spectrograph is fed by an 18-in. siderostat through a 12-in. photovisual lens of focal length 21 ft. The upper half of the spectrum is focused on to the photographic plate and is used in the customary way, the lower half being deflected towards the side of the spectrograph camera by means of a right-angled prism. This is adjusted so that the deflected spectrum is also in focus at the scanning slit of the photometer. The light from this slit, which is about 0·03 mm. wide, is received by a short-focus convex lens fixed at a distance from the slit equal to its focal length. The parallel beam of light so obtained from a narrow section of the spectrum is directed again by a second right-angled prism to the photo-cell. The details of the instrument are shown by the three diagrams. Although primarily designed for use in solar line-contour work, its sensitivity can be easily reduced and thus its stability increased. For use in certain visual observations, a less sensitive prototype of the instrument has been constructed. It is suggested that a photometer of the type described could deal with various problems of interest to geophysicists.

Sunspot Observations in Spain

A summary of the observations made at Madrid Observatory during 1951 is given by E. Gullón in the *Boletín Astronómico Del Observatorio De Madrid* (4, No. 5; 1952). As in previous years, the observations were made with the Zeiss spectroscope, mounted in the equatorial Grubb telescope with object glass 20 cm. aperture and focal length 3 m. Six tables are published giving the usual details regarding the observations, and there are many illustrations showing large prominences at various times during the year. These are followed by a number of tables giving details of the observations of sunspots made in 1951 in the observatories of Madrid, Valencia, Cartuja (Granada) and Ebro. All the observations made at the different observatories have been sent each quarter to the International Bureau at Zurich, following the precedent of previous years.

Factory Problems

The latest publication by the Institute of Personnel Management in its series of Occasional Papers is one by Wilfred Brown. The author is the managing director of the Glacier Metal Co., which, for many years, has been conducting a serious attempt to understand the managerial and social problems of to-day. In 1948 it undertook, with the Tavistock Institute of Human Relations, a joint sociological research into such matters. One of the results of this research has been the emergence of a series of defined ideas and concepts stating the social processes in use in its factories. The paper is an attempt to describe those ideas and concepts upon which its leaders, managers, technicians, shop stewards and representatives are basing their methods of dealing with the day-to-day technical, economic, production and administrative problems encountered in operating the company. The Company is continuing its research activities in this field, and believes that the work so far done is but a start in the long process of achieving a greater degree of scientific objectivity in the social affairs of a factory. The paper, "Some Problems of a Factory", may be obtained from the Institute of Personnel Management, Management House, Hill Street, London, W.1.

Courtaulds' Scientific and Educational Trust Fund: Awards

The trustees of the Courtaulds' Scientific and Educational Trust Fund have announced the award for 1953 of the following postgraduate research scholarships in a branch of science related to the textile, plastics and allied industries, the awards being worth £400 and tenable for one year at the institute shown: D. W. Bannister, University of Oxford (renewal of 1952 award); C. S. Chadwick, Manchester College of Technology (renewal of 1952 award); P. G. Francis, University of Reading; A. J. Head, Birkbeck College, London; R. M. Hochstrasser, University of Edinburgh; D. Margerison, University of Liverpool; R. I. C. Michie, Manchester College of Technology; Miss E. R. Robertson, University College, Dundee; P. T. Speakman, University of Oxford (renewal of 1952 award); B. D. Stead, University of Birmingham (renewal of 1952 award); R. Stephens, University of Birmingham. Postgraduate research scholarships in textile technology, worth £320 for the first year and £360 for the second year (except where otherwise shown), have been awarded as follows: C. B. Chapman, University of Leeds; G. E. Cusick, Manchester College of Technology; A. F. Greenwood, University of Leeds; D. R. Hardisty, Manchester College of Technology; F. K. Hall, University of Leeds (renewal of 1951 award for one term); H. B. Hallows, Manchester College of Technology (renewal of 1951 award for one year); G. M. Jeffrey, University of Leeds (renewal of 1951 award for one year).

Eighth International Congress of Botany

The Eighth International Congress of Botany will be held in Paris during July 2–14, 1954, in conjunction with the hundredth anniversary of the

Botanical Society of France. Besides the plenary meetings, the Congress will consist of section meetings which will be divided into two categories: those devoted to organized colloquia on definite topics; and those devoted to sundry communications. For the former, general reports not exceeding twenty thousand letters and original communications not exceeding five thousand letters, and for the latter, summaries not exceeding two thousand letters, may be submitted, and they should all be sent to the respective section secretaries before January 15, 1954. In addition to the Congress events, there will be meetings of a number of Commissions of the International Union of Biological Sciences. The official languages of the Congress will be English and French, but if sufficient advance notice is given, interpreters can be arranged for those who may wish to speak in German, Russian or Spanish. A large number of excursions are being organized, some of which, including those to North and West Africa, will take place before the Congress, and early notice is requested of those who wish to participate. The fee for those taking part in the Congress will be 5,000 francs (about £5 or 15 dollars), with half-rates for students and for those merely accompanying participants. All correspondence on matters not relating to the individual sections should be addressed to the Secrétariat Général, 8e Congrès de Botanique, C.N.A.M., 292 rue Saint-Martin, Paris 3e, from which registration forms, programmes and all further information can be obtained.

The Night Sky in September

New moon occurs on Sept. 8d. 07h. 47m., U.T., and full moon on Sept. 23d. 04h. 15m. The following conjunctions with the moon take place: Sept. 1d. 16h., Jupiter 4° S.; Sept. 5d. 08h., Venus 0·3° N.; Sept. 6d. 17h., Mars 3° N.; Sept. 11d. 22h., Saturn 8° N.; Sept. 29d. 03h., Jupiter 4° S. In addition to these conjunctions with the moon, the following conjunctions of planets with bright stars occur: Sept. 13d. 01h., Mars 0·8° N. of Regulus; Sept. 23d. 09h., Venus 0·4° N. of Regulus; Sept. 29d. 17h., Mercury 1·6° N. of Spica. Mercury, a morning star at the beginning of the month, is in superior conjunction on September 7, afterwards becoming an evening star, but is too close to the sun during the month for favourable observation. Venus, a morning star, rises at 1h. 55m., 2h. 30m. and 3h. 10m. on September 1, 15 and 30, respectively; its stellar magnitude is about − 3·4, and the visible portion of the illuminated disk varies between 0·78 and 0·86. Mars, a morning star, rises about 3h. 30m. during the month and can be seen in the constellation Leo, through which it has an eastward movement; towards the middle of September it lies a little north of Regulus. Jupiter rises at 22h. 45m., 22h. and 21h. on September 1, 15 and 30, respectively, its stellar magnitude being about − 2. During the month it moves eastward from north of ζ Tauri towards the constellation Gemini, and this movement is easily detected. Saturn sets at 20h. 15m. on the first of the month, and an hour after sunset during the middle of the month, after which it draws too close to the sun for favourable observation. Occultations of stars brighter than magnitude 6 are as follows, observations being as if made at Greenwich: Sept. 27d. 2h. 30·9m., 17 Taur. (*D*); Sept. 27d. 3h. 05m., 23 Taur. (*D*); Sept. 27d. 3h. 33·5m., 17 Taur. (*R*); Sept. 27d. 3h. 43·1m., η Taur. (*D*); Sept. 27d. 4h. 15·5m., 23 Taur. (*R*); Sept. 27d. 4h. 37·5m., 27 Taur. *m.* (*D*); Sept. 27d. 4h. 57·6m., η Taur. (*R*); Sept. 28d. 23h. 50·1m., 125 Taur. (*R*); *D* and *R* refer to disappearance and reappearance, respectively. Autumnal equinox takes place on September 23d. 08h.

Announcements

The Institution of Metallurgists announces that the Duke of Edinburgh will open the Platinum Metals Exhibition organized by the Institution at Grosvenor House, London, on October 19. The Exhibition is being held to mark the 150th anniversary of William Hyde Wollaston's announcement of his discovery of palladium, and will be open to the public during October 22–24.

Mr. William E. Miller, editor of the *Wireless World*, has been re-elected president of the British Institution of Radio Engineers for a second term of office. The senior award of the Institution, the Clerk Maxwell Premium, has been awarded for 1952 to Dr. Charles Süsskind, of the Microwave Laboratory, Stanford University, for his paper on "Obstacle-Type Artificial Dielectrics for Microwaves", published in the Institution's *Journal* of January 1952.

A Faraday Society General Discussion on "Dyeing and Tanning" will be held in the Department of Chemistry, University of Leeds, during September 8–10. The Discussion will be divided into two parts, devoted to rate processes and structural effects, respectively, and will be preceded by a general introduction by Sir Eric Rideal. Further information can be obtained from the Secretary, Faraday Society, 6 Gray's Inn Square, Gray's Inn, London, W.C.1.

The British Society of Rheology is arranging a symposium on "The Mixing of Thick Liquids, Pastes and Slurries", to be held in the Main Chemistry Lecture Theatre of the Imperial College of Science and Technology, London, on September 25. The symposium will be preceded by the annual general meeting of the Society. Admission to the symposium is free, without ticket. Further information can be obtained from the Honorary Secretary, British Rheological Society, Flat H 12, Sloane Avenue Mansions, London, S.W.3.

The eleventh annual meeting of the Electron Microscope Society of America will be held at the Pocono Manor Inn, Pocono Manor, Pennsylvania, during November 5–7. Programmes with abstracts of papers to be presented will be available after October 15 from the programme chairman, A. R. T. Denues, Sloan-Kettering Institute for Cancer Research, 444 East 68th Street, New York 21, N.Y. Local arrangements are being made by Kenneth S. McCarty, Veterans Administration Hospital, 130 West Kingsbridge Road, Bronx, New York.

In the article entitled "International Electro-Acoustics Congress" in *Nature* of August 1, p. 189, it is stated that the International Committee of Acoustics is "an offshoot of Unesco". This is not correct. The Committee belongs to the International Union of Pure and Applied Physics, and it received a subvention this year from Unesco through that Union and the International Council of Scientific Unions.

Erratum. In the communication entitled "Biogenesis of Alkaloids of Solanaceae" by Sir Robert Robinson in *Nature* of August 22, p. 344, penultimate paragraph, for "this base" read "cuskhygrine".

IMPURITY PHENOMENA IN PHYSICS AND CHEMISTRY

A THREE-DAY symposium on "Impurity Phenomena" was held at the Knoll's Research Laboratory of the General Electric Co., Schenectady, during June 16–18, arranged by the Division of Physical and Inorganic Chemistry and the Eastern New York Section of the American Chemical Society in conjunction with the Division of Solid State Physics of the American Physical Society. About three hundred persons attended the symposium, and it proved a very successful meeting-ground for chemists and physicists active in a field in which contributions of both groups have been significant.

The first session, under the chairmanship of Dr. F. E. Williams (General Electric Research Laboratory), dealt with general aspects of impurity phenomena. Prof. F. Seitz (University of Illinois) set the stage for the symposium by reviewing the range of crystal imperfections. From such a point of view, imperfections in a perfect crystal include lattice vibrations or phonons; free electrons and holes; excitons (a neutral electron–hole combination); vacancies at lattice sites and interstitial ions or atoms in the lattice; *F*-centres; foreign or impurity atoms or ions; and dislocations. Light interacting with such a crystal is treated in terms of photon impurities in the lattice. Prof. Seitz went on to say that the significant advance of recent years has been in the disentangling of these separate imperfections and in showing their inter-relationships. Thus *F*-centre formation can be shown to be a result of the interaction of several imperfections—dislocations associating to form ion vacancies, free electrons being produced and then being trapped at the negative ion vacancies. The following paper, by Prof. C. Wagner (Massachusetts Institute of Technology), dealt with the role of lattice defects for solubility problems in ionic crystals and stressed the similarities with solubility problems of ideal and non-ideal aqueous solutions. Among the problems cited was the decrease in the solubility of silver sulphide in zinc sulphide in the presence of cuprous sulphide. In general, the solubility of a solute 2 in the solvent crystal 1 will be decreased by presence of a solute 3 if both solutes have either a greater or a smaller cation/anion ratio than the solvent, and thus dissolution of solutes 2 and 3 results in the formation of the same type of defect, either interstitial ions or vacancies. The last paper of the general session was entitled "Evidences of Crystalline Imperfections in Nuclear Magnetism" and was presented by Prof. R. V. Pound (Harvard University). Nuclear paramagnetic resonance has become a tool for the study of the solid state, and some effects were described. The relaxation times measured can indicate the strength of the heat contacts between the spin system and the lattice, and these are modified in the presence of impurities. Paramagnetism associated with lattice constituents was discussed, and the presence of dislocations and their density may also be investigated for 'perfect' and 'work-hardened' crystals.

The second session, under the chairmanship of Dr. P. Pringsheim (Argonne National Laboratory), dealt with the coloration of solids by impurities. Dr. J. H. Schulman (Naval Research Laboratory) indicated how impurities can influence markedly the colorations produced by ionizing radiations on solids. The impurities may change the number of crystal defects due to mis-match in ion size or polarization properties. They may change the concentrations of negative and positive ion vacancies due to electrostatic charge differences between the impurities and host crystal constituents, and they may act as traps for electrons and holes. Since the concentrations required for such effects may be very small, there is a field of investigation unfolding to disentangle the effects mentioned from those associated with host crystals of ultra-purity. Prof. W. A. Weyl (Pennsylvania State College) read a paper on metals in the atomic state in glasses, contrasting with their behaviour in solids. The coloration of alkali halides by the presence of colloidal metal was described by A. B. Scott, W. A. Smith and M. A. Thompson (Oregon State College). Alkali halides containing excess alkali metal, on moderate heating, develop absorption bands due to colloidal metal of estimated particle size 10–50 A. After extended heat treatment, the particle size becomes increased, and scattering of the light then occurs. J. J. Markham (Johns Hopkins University) closed the session with a synthesis of some of the properties of colour centres. He discussed the interaction of colour centres with their environment and separated two classes of interactions—the macroscopic, which affect the rates at which bands are formed during irradiation and affect the bleaching rates both in the light and in dark, and the microscopic, which affect the shape of the band and the bleaching properties at very low temperatures. The question of whether there exists more than one type of *F*-centre depending on the method of preparation still remains open.

The third session, with Dr. H. W. Leverenz (R.C.A. Laboratories) as chairman, dealt with activators in luminescent crystals. Prof. R. Ward (University of Connecticut) spoke on the chemistry of phosphors and on the increasing necessity for ultra-high purity in the preparation of the chemicals. He discussed certain luminescent systems such as zinc sulphide/copper in which the concentration of copper impurity markedly affects the colour of the luminescence. The need for inclusion of compensating ions to satisfy electrical neutrality was emphasized, and he ended with a discussion of recent work on the luminescence of materials with perovskite structure. Dr. C. C. Klick (Naval Research Laboratory) spoke on emission and absorption associated with luminescent centres at low temperatures. The main features at low temperatures are: that the bands remain broad; the emission and absorption band-widths vary as the square root of the temperature at high temperature but vary at a lesser rate and approach a constant value at low temperatures; and some systems show an emission composed of equally spaced 'lines'. Certain of these features could be explained by treating the luminescent centre as a one-dimensional harmonic oscillator. Vibrational frequencies in the range 10^{12}–10^{13} c./s. are obtained on the basis of such a model. Dr. D. L. Dexter (University of Rochester) spoke on the theory of sensitized luminescence in solids. To obtain sensitized luminescence one adds to the host crystal two sets of activators. One, the sensitizer, possesses strongly allowed optical transitions and absorbs the incident radiation, the other, the activator, has a forbidden transition; and the two are chosen so that the emission band of the sensitizer overlaps the absorption band of the activator. There is then a radiationless transfer of energy from the sensitizer to the activator. The extent of the sensitized region surrounding each sensitizing centre was indicated as about thirty lattice sites with a general increase in sensitivity in the region of a thousand. The theory of the luminescence of impurity-activated ionic crystals was discussed by Dr. F. E. Williams (General Electric Research Laboratory), who indicated how refinements to the recent theory of the luminescence of thallium-activated potassium chloride improve agreement between theory and experiment. The angular dependence of the wave function of the excited state affects the luminescence peak-shape. An evaluation of the first-order perturbation of the energies of the activation ions by the crystal field indicates that it is appreciably different for the ground and excited states, thus altering the position of the emission and absorption peaks. Dr. R. H. Bube (R.C.A. Laboratories) gave a general paper on traps and trapping processes and their importance for luminescence theory, particularly in affecting frequence response. Traps due to host crystal imperfections and due to the presence of impurities have been separated and studied for sulphide and silicate phosphors.

The next session was devoted to the photographic process. In his introduction, the chairman, Dr. J. A. Leermachers (Kodak Research Laboratories) indicated the scope of the photographic process, its dependence on rate processes and the problems connected with the primitive sensitivity and the superimposed chemical effects. Dr. F. Urbach (Kodak Research Laboratories) presented a paper, read by Mr. D. Pearlman, on some effects of inorganic impurities on silver halide crystals. Slight traces of alkaline earth metals in silver bromide produce luminescence at 77° K. with long afterglow. In addition, very slight amounts of nickel and gold in silver bromide have been found to produce marked effects. Dr. G. W. Luckey (Kodak Research Laboratories) discussed recent measurements performed on the vacuum photolysis of silver bromide. The pressure of photolytic bromine was measured for slabs, crystals and evaporated films and the quantum yield—that is, the number of bromine atoms produced per quantum of light absorbed—was found to increase with decreasing wave-length. The results showed vacuum to be a good halogen acceptor, and the quantum yield is near unity when the concentration of electron traps is high. For thick specimens the decomposition that produced measurable quantities of bromine occurred in a surface layer of the crystals of thickness approximately 0·3 micron. Dr. W. West (Kodak Research Laboratories) read a paper on the effect of impurities on the optical sensitization of the photographic emulsion. It is well known that the general level of sensitivity of silver halide photographic emulsions may be increased by the presence of chemical impurities on the surface, as for example sulphur, which may be introduced during the emulsion-ripening process. There are also other sensitizers—for example, certain dyes—which confer sensitivity in the long wave-length region and the general level of activity of which is governed by the presence of slight traces of additional impurities which may increase sensitivity (super-sensitizers) or decrease sensitivity (anti-sensitizers). A general mechanism associated with these processes was presented. The session closed with a paper by F. W. H. Mueller, H. Hoerlin and E. T. Larson (Ansco Division) describing the sensitization of X-ray emulsions by very small quantities of a divalent salt such as lead or cadmium bromide.

"Analysis for Trace Impurities" was the subject of the fifth session under the chairmanship of Prof. W. D. Cooke (Cornell University). Dr. M. G. Inghram (University of Chicago) outlined the use of the mass spectrometer for trace element determination with particular emphasis on the isotopic dilution method. Analysis for trace impurities by neutron activation was described by W. A. Brooksbank, G. W. Leddicote and H. A. Mahlman (Oak Ridge National Laboratory), and the sensitivity of the method in several instances was cited. Details were described of the recently inaugurated public service whereby specimens may be submitted for analysis at the Oak Ridge National Laboratory. A second paper, by W. A. Brooksbank and G. W. Leddicote, described procedures for separating out trace impurities by ion-exchange methods for use in conjunction with the neutron-activation techniques. The combination provides an extremely sensitive and specific method for the determination of small quantities of the rare earths and alkali elements in the presence of each other. Dr. L. Strock (Sylvania) followed with a paper on the extension of the sensitivity of emission spectroscopy both by physical means within the light source and by means external to the source. The methods have been used for impurity estimation in germanium in the 10^{-6} to 10^{-7} weight per cent range—that is, 1 part impurity in 10^{8}–10^{9} atoms. C. A. Streuli and W. D. Cooke (Cornell University) discussed the application of a polarized mercury-pool electrode to polarography, indicating its advantages coupled with greater sensitivity compared with the dropping-mercury electrode. Polarograms for several metals were shown with a sensitivity of about 20×10^{-9} gm./ml.

The final session, under the chairmanship of Dr. A. H. White (Bell Telephone Laboratories), was devoted to papers discussing the role of impurities in semi-conductors and transistors. The equilibrium thermochemistry of solid and liquid alloys of germanium and silicon was discussed by C. D. Thurmond and J. D. Struthers (Bell Telephone Laboratories). The solubilities of antimony and copper in germanium were determined. Dr. R. N. Hall (General Electric Research Laboratory) discussed the segregation of impurities during the growth of germanium and silicon crystals. By a radiographic technique this segregation was observed and its dependence on rate-growth and crystal orientation determined. Since this dependence is generally much greater for donor impurities than it is for acceptors, it makes possible the growth of crystals containing large numbers of *p–n* junctions. H. M. James and A. S. Ginsberg (Purdue University) read a theoretical paper on the effects of impurity atoms on the band structure of alloys and semi-conductors on the basis of a one-dimensional alloy or crystal. The sharply defined impurity band for a crystal with the regularly placed impurities becomes replaced by a broadened region of high energy-level density when the impurities are randomly arranged. E. Burstein, E. E. Bell and J. W. Davisson (Naval Research Laboratory) and M. Lax (Syracuse University) discussed some optical investigations of impurity-levels in silicon at the temperature of liquid helium. Optical absorption by neutral impurities may involve two things: photo-ionization of bound-charge carriers, which is accompanied by photoconductivity; and optical excitation of bound-charge carriers from the ground-state to higher energy-states which appears as relatively narrow bands at wavelengths beyond the photo-ionization limit. Such transitions are observed in boron-doped specimens at 28·7, 31·2 and 36·0 microns, which are attributed to 1*s*–4*p*, 1*s*–3*p* and 1*s*–2*p* transitions respectively. J. A. Burton, G. W. Hull, F. J. Morin and J. C. Severiens (Bell Telephone Laboratories) described the effects of nickel and copper impurities on increasing the rate of recombination of holes and electrons in germanium. The dependence of lifetime on resistivity at room temperature is consistent with the Shockley–Read–Hall theory of recombination at traps near the middle of the forbidden band. The capture cross-section of these traps for holes and electrons were estimated. The final paper, by Dr. S. R. Morrison (University of Illinois), described measurements on the changes of surface conductivity of germanium with ambient atmosphere, in which the changes of conductivity were correlated with changes in the space charge layer at the free surface of the semi-conductor.

The majority of the papers read at the meeting will be published in the November issue of the *Journal of Physical Chemistry*. W. Grattidge

INSTITUTE FOR THE ENCOURAGEMENT OF SCIENTIFIC RESEARCH AND AGRICULTURE, BRUSSELS

REPORT FOR 1952

THE annual report for 1952 of the Institute for the Encouragement of Scientific Research and Agriculture, Brussels*, records forty-one grants made during the year, totalling 99,894,670 Belgian francs. Of this sum, 16,870,000 francs went to the Committee for Mapping the Soil and Vegetation of Belgium for systematic studies of the pedological character of the soils and completing the pedological map. A grant of 8·19 million francs went to the Committee for the Study of the Disease and Nutrition of Cattle, partly for research on trichosomiasis and brucellosis and partly for investigations on nutrition. The National Centre for Grass and Fodder Research received 7·35 million francs for research on the rational and intensive exploitation of grass in Belgium, and the National Centre for Metallurgical Research 7·18 million francs in support of its programme of research on the determination of gas and the influence of the presence of gas in metals, the determination of occlusions in steel, spectral analysis and metallurgical physics. These investigations have included comparative studies on the determination of nitrogen in ferrous alloys, cast iron and special steels, the deoxidizing action of silicon, aluminium, silico-aluminium, silico-calcium and magnesium, and micro-kinematographic studies of fracture by bending. The National Committee for the Study of Fruit Culture received a grant of 5,632,250 francs in support of a programme of work bearing on the rational development of orchards, for researches relating to soils and manures, plant investigations, including systematic studies on plums and apples, cytological research, and researches on fruit pathology. A grant of 4·45 million francs went to the Committee for the Scientific and Technical Study of Milk and its Products for work in this field, including the preservation of milk, the changes occurring in butter on storage in refrigerators, the microbial floral and chemical composition of different makes of cheese, and studies on the preparation of acidified milks such as yoghourt. 3·81 million francs to the Technical and Scientific Centre of the Belgian Glass Industry were for the continuation of investigations on the annealing of glass, on the physical and chemical properties of different glasses and on the manufacture of mirrors.

The Centre for Studies and Research into Hydroponics received 2,525,000 francs for its investigations on the behaviour of certain agricultural and horticultural plants on cultivation in mineral substrata and on the mineral nutrition of vegetables; 2,312,500 francs went to the Belgian Centre for the Study and Documentation of Water for research on water treatment, on rust and corrosion and on effluents; and 2,276,500 francs to the Committee for the Study of Metallic Creep at Ordinary Temperatures for further work on creep in hardened steel. The Centre for the Study of High Polymers received 2,262,000 francs for chemical and physico-chemical investigations on high polymers, and the Committee for the Study of Metallic Creep at High Temperatures 2,088,000 francs for investigations on the creep of steel above 575° C.; 2,040,000 francs were granted to the Committee for the Study of Organic Matter in Belgian Soils for investigations on the degradation of certain soils through loss of structure, and 1,892,000 francs for investigations into animal and vegetable physiology using the radioactive isotope technique. Research on the machinability of steel received a grant of 1,849,000 francs; 1,781,300 francs went to the Centre for Scientific and Technical Research of the Metal Industry for casting research; 1·7 million francs for pathological and genetical research on the potato; 1,460,000 francs for corrosion research, including cathodic protection and the study of descaling treatments; 1·24 million francs to the Tobacco Commission of the Provincial Agricultural Committee of Western Flanders for research on the commercial cultivation of tobacco; 1·13 million francs for research on the cultivation, conservation and utilization of medicinal and aromatic plants; and 1·12 million francs to the Committee for Research into Cereal Diseases.

Among smaller grants may be noted those for cotton research (922,500 francs), for investigations on the culture of mushrooms (770,000 francs), for research on the sensitization and granulation of photographic emulsions (700,000 francs), for scientific and technical research at high pressures (595,000 francs), for welding research (531,000 francs), for investigations on the specific heat of organic compounds (360,000 francs), for microbiological investigations on vinegar manufacture (111,250 francs) and 270,000 francs for investigations on the cultivation of maize in Belgium. The Belgian Centre for Naval Research received 450,000 francs in support of research on thermal and acoustic insulation, while 722,000 francs were granted to the Research Centre of the Belgian Ceramic Industry for investigations on the plasticity of pastes and viscosity of slips used in ceramics and 712,500 francs to the Technical Centre of the Textile Industry for investigations on the oiling of jute fibres. A list of publications relating to assisted researches appearing during the year is included.

DEPARTMENTS OF TEXTILE INDUSTRIES AND COLOUR CHEMISTRY AND DYEING, UNIVERSITY OF LEEDS

REPORTS FOR 1950–52

THE Advisory Committee on the Departments of Textile Industries and Colour Chemistry and Dyeing of the University of Leeds has made two reports, for the sessions 1950–51 and 1951–52, respectively, to the Worshipful Company of Clothworkers of the City of London[*]. That for the session 1950–51 refers to continued excessive pressure on accommodation. In the Department of Textile Industries, where students will in future be able to read for honours degrees in textile physics, textile chemistry or textile engineering, the equipment of all sections is now in excellent condition, permitting both teaching and research on the most modern machinery. In the textile physics section the electron microscope has been used for examining keratin and also the disintegration of cellulose fibres in strong mineral acids. A further laboratory has been equipped for teaching and routine work on the examination of fibres by the microscope and other optical methods, and in the weaving section progress is reported in studies of cloth-setting and the influence of structural differences, in respect of yarn, weave interlacing and sett, on the properties of woven fabrics. In the finishing section, besides work on the action of metal amines on proteins, the properties of viscose rayon containing vinyl polymers have been examined with the object of developing methods for producing dimensionally stable rayon fabrics. Work in the textile chemistry section has dealt with the behaviour of the alcohols and esters of wool wax at the air–water interface, variation in sulphur content and plasticity among wool fibres, the swelling of keratin, the dissolution of wool and the action of neutral salts on animal fibres. In the Department of Colour Chemistry and Dyeing, progress is reported in the study of the self-union of organic compounds such as mesobenzanthrones and pyrazoleanthrones, a satisfactory explanation of the mechanism of formation of flavanthrone in the alkali fusion of 2-aminoanthroquinone has been obtained, and an investigation of the substitution of cinnoline, phthalazine, quinoxaline and quinazoline by anions was commenced. Lists of publications are included.

The report for the session 1951–52 reports a record number of students in the Department of Textile Industries and a further increase in students in the Department of Colour Chemistry and Dyeing, where two new scholarships for research in colour chemistry have been endowed, as well as two new studentships. In the textile physics section an ultrasonic technique was being applied to both keratin and cellulose, and a new type of rotating vacuum seal being developed for use in interpreting the molecular structure of keratin. In the textile chemistry section conclusive proof has been obtained that the variation in plasticity among the fibres in a single staple is associated with the age of the follicles from which they are derived, and the formation of cross-linked polymers inside wool fibres by co-polymerization of compounds such as divinyl ether and methacrylic acid has been studied, while methods were being devised for weighting the different types of side-chains with heavy metal atoms so that their distribution could be determined by X-ray examination of the treated fibre. Two quantitative methods of estimating the amount of medulla in hairy wools have been discovered, and in textile engineering the performance of the prototype electronic mule has been so satisfactory that the first large-scale model was being built for trial in a Yorkshire mill. The action of metal amines on wool and other proteins and the influence of various treatments on the dyeing properties of wool was being examined in the textile technology section in co-operation with the Department of Colour Chemistry and Dyeing. Other problems being investigated included the bleaching of pigmented fibres, the setting of nylon, and the assessment of damage in textile materials.

In the Department of Colour Chemistry and Dyeing work on the constitution of the anthraquinone–carbazole dyes and the mechanism of their formation points to the possibility of a general theory of reactions involving condensation of organic compounds by hydrogenation. A study of the condensation of amines with aromatic nitro-compounds was commenced, and an investigation of the reduction of anthraquinone derivatives with alkaline sodium dithionite, which indicates an unexpectedly frequent formation of anthrones, has a direct bearing on the application of vat dyes. Work on the preparation and orientation of the *tert.*-butyl derivatives of acenaphthene was completed, and that continued on the resolution of *dl*-mandelic acid and its derivatives into optically active forms on wool and on the chemical and physical factors concerned in the application of dispersed dyes to cellulose acetate rayon.

A NATURALIST IN SOUTHERN ETHIOPIA

DR. HUGH SCOTT, who has just returned from yet another journey to Abyssinia, has placed in his debt everyone whose scientific interests include this remarkable part of the world. On his expedition of 1948–49, which is dealt with in a recent paper[*], as on his first, Dr. Scott's main purpose was to collect insects at high altitudes; but incidentally he acquired a great deal of information about the country and its inhabitants. Much of the area he passed through was little known and it was exceedingly ill-documented, especially in English; therefore the account that he gives of the topography, vegetation and climate provides, in addition to an account of a naturalist's journey, as fascinating in itself as his account of the Yemen ("In the High Yemen." 2nd edit., 1949), an invaluable background to any biological work concerned with the area traversed. The text is supported by a good bibliography, and a special feature of the paper is the twenty-six plates, illustrating a variety of subjects of interest to the botanist, ethnologist and geographer.

---

[*] Journey to the Gughé Highlands (Southern Ethiopia), 1948–49; Biogeographical Research at High Altitudes. By Dr. Hugh Scott. *Proc. Linn. Soc.*, Session 163, 1950–53. Pp. 85–189 + 26 plates.

Dr. Scott reached Addis Ababa on August 20, 1948; but the unusually heavy rains had done so much damage to the roads he wished to traverse that he was not able to start until October 15. He returned to the capital on January 28, 1949, after a remarkable journey, with no European companion, which took him to within about seventy miles of the Kenya border. His main objective was the high ground west of the Rift Valley, Mt. Damota (10,400 ft.) and the almost legendary Gughé Highlands, rising to 13,780 ft. He continued south through Konso to Yavello and returned to his base up the eastern side of the Rift. It is pleasant to record that on his 1948–49 journey Dr. Scott found public security much better than it had been when he was travelling in the country during 1926–27.

The account of the journey is prefaced by a section on "Biogeographical Considerations", in which Dr. Scott briefly considers the "zones of vegetation in southern Ethiopia" (with special reference to those on the mountains he personally explored) in relation to published information about the biology of mountain country elsewhere in Africa. In this connexion he discusses certain groups of Coleoptera in which he is a specialist; and also the effects of isolation on the evolution of congeneric species, together with the parallel evolution of certain insects along with the high-mountain plants with which they are so closely associated.

Although his main task in Ethiopia was the collection of observations on and specimens of insects, Dr. Hugh Scott made a most useful botanical collection. Hitherto, nothing much was known of the vegetation of Mt. Damota and the Gughé Highlands, and no collections of plants from these mountains had ever been made. Dr. Scott is to be congratulated on bringing home many plant specimens in such an excellent state of preservation that one might have imagined that they had been taken and prepared under ideal conditions. This, however, is far from the truth, for much of the time that he was at high altitudes, Dr. Scott was working under very austere and unpleasant conditions. The Gughé Highlands in particular are notoriously wet. That Dr. Scott endured "raw, damp weather, with thunder on two nights" when camping at about 10,600 ft. on Mt. Tola, is certainly not reflected in the specimens he obtained.

Botanically the chief interest in the collection is that it comes from an area situated between the Simien Highlands, so well collected by German and French collectors in the first half of the past century, and the highlands of Kenya, the flora of which is now comparatively well known. When Dr. Scott's plant collections are finally worked out, the preliminary determinations of which are listed at the end of his paper, many gaps in our knowledge of the distribution of plants on the mountains of Africa will have been filled.

About half the paper is taken up with the "Description of the Country, with Natural History Notes", to which are added three appendixes. The most important of these deals with the author's archæological and ethnological observations, with special reference to the phallic monoliths of Walămo and Sidămo. These exist in thousands, many of them up to ten feet in height, yet they are very little known. In his main narrative Dr. Scott gives full rein to his very wide natural history and human interests. They range from the Addis Ababa gardens, and the butterflies and birds that frequent them, to the spread of prickly pear, the practices of the local bee-keepers and the uses made of the local bamboos. He found almost everywhere that extensive inroads had been made into the native vegetation, and that in places cultivation had been carried right up to 10,000 ft. Yet in parts of the south, splendid primary forests still exist. He gives, of course, special importance in his narrative to the mountain massifs that were his principal objective; and anyone who has had the good fortune to be a pioneer in any branch of biological exploration in an unknown locality will live again with him the enthusiasm with which he toiled up those distant slopes.

GRAZING BEHAVIOUR OF BULLOCKS

Environmental factors which can influence the behaviour of a herd of bullocks may be divided into, first, the natural conditions of climate, including seasonal changes and weather; and secondly, the system of management of the bullocks.

Methods of management, the ways in which grass, in different quantities and of varying quality and palatability, is offered to the beasts, fall into two categories. The grazing may be uninterrupted from day to day, as in free-range and rotational systems. Other methods exercise some form of daily control over the quantity of herbage allowed the bullocks, which may be a control of area or of time allowed on the grass. In a recent article, J. C. Tayler, of the Grassland Research Station, Stratford-on-Avon, has described the behaviour of Hereford-cross bullocks under two management systems in these categories (*Brit. J. Animal Behaviour*, 1, No. 2; April 1953).

These studies have shown that the grazing behaviour of bullocks in a herd may be regarded as following a repeated daily pattern closely related to environmental factors. Of these factors, the varying hours of daylight throughout the year produce seasonal changes in the basic pattern. Weather and other disturbances may affect the grazing pattern in many minor ways; but, next to seasonal effects, those resulting from the system of management seem to be the most important.

Under the two systems of management, 'rotational' and 'strip' grazing, changes in behaviour resulting from the system may be due to the herbage, through its physical, internal effect as, for example, in winter grazing on limited areas. They may also be due to a daily disturbance as was shown in the 'strip folding' system. Under this system of management the animals show definite signs of appreciating that a fresh supply of grass will be offered later in the morning and delay their main grazing period up to six hours later than it would occur under undisturbed conditions.

Studies of behaviour during the past three years have been used at the Grassland Research Station for improving the accuracy of results in live-weight-increase experiments where bullocks are weighed straight from pasture. A knowledge of their behaviour pattern makes it possible to remove the bullocks from pasture for weighing when the 'fill' of grass in the rumen is approximately the same at each weighing.

HÆMOGLOBIN IN FUNGI

Occurrence of Hæmoglobin in Yeast and the supposed Stabilization of the Oxygenated Cytochrome Oxidase

At an early stage of the work on the components of cytochrome[1], special experiments were devised for the study of the absorption spectra of these pigments in the presence of hæmoglobin or myoglobin. This was found necessary for the proper understanding of the absorption spectra of cells and tissues where these pigments may co-exist.

Spectroscopic study of yeast cells in presence of added exogenous hæmoglobin. For this purpose a few drops of dilute laked blood or hæmoglobin are added to a suspension of baker's yeast and the mixture is examined in the usual way with a low-dispersion microspectroscope, or hand spectroscope. The amount of blood added should give a concentration at which the distinct bands of oxyhæmoglobin are replaced, on deoxygenation, by the diffuse and faint band of hæmoglobin. Sharp absorption bands are shown by cytochrome only in the reduced state, and by hæmoglobin only in the oxygenated state. Thus, when air is passed through such a mixture the four bands of the reduced cytochrome disappear and are replaced by the two bands of oxyhæmoglobin. When aeration is interrupted and the oxygen of the suspension is used up in the respiration of the yeast, the sharp absorption bands of reduced cytochrome reappear while the two distinct bands of oxyhæmoglobin are replaced by the faint band of hæmoglobin which does not mask the absorption bands of cytochrome.

On the addition of cyanide to an aerated yeast suspension containing hæmoglobin, the bands of reduced cytochrome can be seen side-by-side with those of oxyhæmoglobin. Cyanide, by inhibiting the reoxidation of the reduced components of cytochrome, prevents the utilization of oxygen in yeast respiration and thus protects oxyhæmoglobin from deoxygenation. Under these conditions the α-band of oxyhæmoglobin, which lies at about 577 mμ between bands *a* and *b* of cytochrome, appears as a narrow but distinct band, whereas the β-band, which lies at about 542 mμ, is seen as a diffuse absorption between cytochrome bands *c* and *d*.

For the same reason the addition of cyanide enables the absorption bands of oxymyoglobin to be seen together with the bands of reduced cytochrome in a slice of perfused pigeon-breast muscle, which normally, owing to its high respiratory activity and the difficulty in arranging efficient aeration, has its myoglobin in the deoxygenated state and therefore not easily recognizable. The difficulty in the aeration of such a compact tissue can be temporarily overcome by the addition of a little hydrogen peroxide which, being decomposed by catalase in the muscle tissue, liberates within the slice a sufficient quantity of molecular oxygen for the oxidation of cytochrome and oxygenation of myoglobin[1].

It was the failure on the part of MacMunn to recognize the presence of hæmoglobin (myoglobin) in the perfused pigeon's breast muscle and his wrong assumption that myohæmatin is the sole colouring matter of this tissue that gave rise to the polemical discussion between him and Hoppe-Seyler. This unfortunate discussion was ultimately responsible for the complete disappearance of myo- or histohæmatin from scientific literature and for the delay of more than forty years in the recognition of the fundamental importance of hæmatin compounds in the catalysis of intracellular respiration[1].

The spectroscopic study of yeast in presence of added or exogenous hæmoglobin summarized above will be referred to later in the interpretation of absorption bands which, in addition to those of cytochrome, may occur in cells of certain micro-organisms.

The absorption band at 583 mμ and Warburg's theory of stabilization of an oxygenated 'respiratory ferment' or cytochrome oxidase. To Warburg and Haas[2] we owe an interesting observation that a thick suspension of baker's yeast, deprived so far as possible of metabolites and saturated with oxygen, reveals the presence of a weak but sharp absorption band in the yellow region of the spectrum at about 583 mμ. As soon as the current of oxygen is interrupted, this band disappears and is replaced by those of the reduced components of cytochrome. However, if cyanide is added to the yeast suspension saturated with oxygen, the band at 583 mμ persists and can be seen at its full strength side by side with the bands of reduced cytochrome. In the presence of carbon monoxide the band in the yellow region disappears and, according to Warburg and Haas[2], is replaced by a diffuse band lying between 590 and 600 mμ, where it can be detected photoelectrically.

As to the nature of the compound responsible for the band at 583 mμ, Warburg[3] put forward the view that it is the oxygenated ferrous complex of the 'respiratory ferment'. This view, according to him, is supported by their findings (1) that this band lies within the region of the spectrum where the α-band of the 'respiratory ferment' should be present, (2) that the 'reduction' of this oxygenated complex like that of the oxidized 'respiratory ferment' is prevented by cyanide, and (3) that in the presence of carbon monoxide the band at 583 mμ appears to be shifted towards the red end of the spectrum into the region (590–600 mμ) occupied by the α-band of the photochemical absorption spectrum obtained by Kubowitz and Haas[4] for the carbon monoxide compound of the 'respiratory ferment' of *Torula utilis* and *Acetobacter pasteurianum*. This study led Warburg[5] to the conclusion that the primary reaction in aerobic or 'oxygen respiration' is the formation of the addition product between oxygen and the ferrous atom of the 'respiratory ferment' and that the oxygenated ferrous 'respiratory ferment' varies in the degree of its stability in different cells. In yeast cells he concludes that it is comparatively stable and therefore susceptable to direct spectroscopic observation (band at 583 mμ), whereas in *Acetobacter* the oxygenated ferrous complex is not visible because the iron within this complex rapidly oxidizes to the trivalent state.

The observations summarized above and Warburg's far-reaching conclusions attracted the attention of several workers who have discussed them in their papers, reviews and books. Thus Shibata and Tamiya and their co-workers[6-8], in agreement with Warburg's view, postulated that the first reaction of the ferrous 'respiratory ferment' consists in the formation of an addition complex with molecular oxygen. However, whereas according to Warburg the divalent iron within this oxygenated complex undergoes a more or less rapid oxidation to the trivalent state, according to the Japanese workers the iron, as in oxyhæmoglobin, always remains divalent, and the oxygen taken up by the ferment is transferred to ferrocytochrome oxidase which becomes oxidized to ferricytochrome oxidase. The theory of the non-identity of the 'respiratory ferment' and cytochrome oxidase led them to postulate that the inhibitions of respiration by carbon monoxide and by cyanide are due to the combination of carbon monoxide with the divalent iron of the respiratory ferment and of cyanide with the trivalent iron of cytochrome oxidase. This theory, which ascribes to the 'respiratory ferment' the property of oxygenation very similar to that of hæmoglobin, has been previously examined and found unacceptable[8].

Warburg and Haas's[8] observations and Warburg's theory[9] of a stabilized oxygenated 'respiratory ferment' were also discussed and accepted by Oppenheimer and Stern[10] and by Stern[11], who found in these observations direct evidence for the formation of an oxygenated intermediate complex in all cases of oxidation by molecular oxygen of a ferrous to a ferric compound. In this sense an oxygenated ferrous cytochrome oxidase was also considered by Lemberg and Legge[12] when they discussed the mechanism of the catalytic activity of this enzyme. However, the real interest of this problem lies not in any very short-lived and thus undetectable oxygenated intermediate, the existence of which may be postulated on purely theoretical ground in all oxidation reactions involving molecular oxygen, but in Warburg's theory of stabilization of such an intermediate based upon direct spectroscopic observations of baker's yeast.

Occurrence of the absorption band at 583 mμ in baker's yeast. Of the numerous samples of commercial baker's yeast which I have examined spectroscopically at different times, only two samples, one obtained in 1936 and the other in 1940, revealed the presence of a weak absorption band between 580 and 585 mμ, and with these two samples I was able to confirm the main observations of Warburg and Haas[8]. The facts that the band at about 583 mμ is visible only during very strong aeration, and that it disappears when aeration is interrupted or when the yeast suspension is treated with carbon monoxide, indicate that the compound responsible for this band is in a ferrous oxygenated state. The band at 583 mμ can be observed even in a moderately aerated suspension provided it is kept at about 0° C. or treated with ethyl urethane. In the latter case this band is visible together with the band *b* of cytochrome. In yeast suspensions treated with cyanide the band at 583 mμ remains visible in the presence of the bands of reduced cytochrome but disappears on treating this suspension with carbon monoxide. Finally, in an aerated suspension treated with carbon monoxide the disappearance of the band at 583 mμ, as will be shown, is not directly connected with the appearance of a faint band between 590 and 600 mμ.

Critical examination of the theory of stabilization of an oxygenated 'respiratory ferment' or cytochrome oxidase. Study of the data so far available concerning the band at 583 mμ does not support the theory put forward by Warburg that this band belongs to an oxygenated intermediate complex of the 'respiratory ferment' or cytochrome oxidase. On the contrary, there is strong evidence in favour of the view that the compound responsible for this band is distinct from cytochrome oxidase. This evidence can be summarized as follows.

(1) The band at 583 mμ does not belong to a compound which has an important function in cellular respiration, since this band has been detected in very few strains of yeast and so far has not been observed in the highly respiring cells of *Torula utilis*, *Bacillus subtilis*, *Azotobacter chroococcum*, several species of *Acetobacter*, or in highly active wing muscle of insects, or in mammalian heart muscle preparations which are exceptionally rich in cytochrome oxidase.

(2) The diffuse absorption band which appears between 590 and 600 mμ when the suspension of yeast is treated with carbon monoxide is due to its combination with cytochrome oxidase (cytochrome a_3 [13]). It can easily be observed in cells and tissues which are completely devoid of the band at 583 mμ.

(3) If the band at 583 mμ were to belong, as was suggested by Warburg, to a ferrous oxygenated cytochrome oxidase complex within which the iron undergoes oxidation from a divalent to a trivalent state, cyanide, which forms a very stable compound with the latter, should accelerate and not slow down the deoxygenation of this complex and therefore the disappearance of this band.

(4) The stabilization of an oxygenated cytochrome oxidase even for a very short period, just sufficient for the spectroscopic detection of this complex, would greatly inhibit the catalytic activity of this enzyme.

(5) The reversible inhibition by carbon monoxide of the catalytic activity of cytochrome oxidase does not necessarily imply the existence of a stabilized oxygenated state of the enzyme, considering that carbon monoxide inhibits, in a similar manner, the catalytic activities of hæm and hæmochromogen compounds[14] in different oxidation reactions. The catalytic activity of phenol oxidases which are copper–protein compounds also shows a strong and perfectly reversible, although light-insensitive, inhibition by carbon monoxide[15,16].

Nature of the compound responsible for the absorption band at 583 mμ. The facts that this band appears when the yeast suspension is aerated, disappears when aeration is interrupted or when the suspension is treated with carbon monoxide, and persists together with the bands of reduced cytochrome in the yeast suspension treated with cyanide, suggest that the band at 583 mμ belongs to a ferrous oxygenated hæmoprotein such as oxyhæmoglobin. We shall refer to this compound as endogenous hæmoglobin, using here the term hæmoglobin in its widest sense, namely, as a hæmoprotein compound which in the ferrous state combines reversibly with molecular oxygen. In fact, the observations on yeast cells containing endogenous hæmoglobin are indistinguishable from those carried out on yeast suspensions containing added extracellular or exogenous hæmoglobin which were described in the first part of this article. However, it may be mentioned here that the α-band of the endogenous oxyhæmoglobin, like that of oxymyoglobin, lies nearer the red end of the spectrum than the α-band of blood oxyhæmoglobin. Since the endogenous hæmoglobin occurs in a very low concentration, only the α-band of its oxygenated derivative can be clearly seen, whereas the more diffuse absorption spectra of deoxygenated and carbon monoxide derivatives are not visible. Were the absorption spectrum of the carbon monoxide derivative visible, its α-band would be found in the region of about 575 mμ and not, as was suggested by Warburg and Haas[8], between 590 and 600 mμ.

That hæmoglobin, in a very low concentration, may occur in certain strains of baker's yeast and not in others is not surprising considering that samples of baker's yeast cultivated under different conditions may display very marked differences in their aerobic and anaerobic metabolisms, their cytochrome systems, their enzymic equipment and many other properties[17-19]. The unexpected occurrence of hæmoglobin in a yeast suspension suggested in the first instance the possibility of its being only an accidental extracellular impurity. This possibility was, however, ruled out by the facts that the band at 583 mμ was of the same relative intensity to cytochrome bands throughout a fairly large specimen of pressed baker's yeast, that the yeast cells were thoroughly washed in a large amount of water before examination, and that the position of this band is 60–70 A. nearer the red end of the spectrum than the average position of the α-band of blood hæmoglobins.

Although hæmoglobin is found in all vertebrates, its apparently random distribution among other organisms is one of the peculiarities of this pigment. Thus, among the invertebrates hæmoglobin occurs somewhat haphazardly, being either completely absent in all representatives of large phyla, or present in only a very few species of a phylum, while absent in all other often very closely related forms. Even in the same organism the hæmoglobin content may show very great variation with the age of the organism or with its external conditions. The marked fluctuation in the hæmoglobin content of *Daphnia* has recently been investigated by Fox, Hardcastle and Dresel[21], who have shown that synthesis of hæmoglobin is favoured by oxygen deficiency. Moreover, a lake plankton species of *Daphnia*, which under natural conditions has colourless blood, was found to synthesize hæmoglobin when kept in an oxygen-deficient medium[21].

The occurrence of hæmoglobin in yeast cells is an interesting addition to the range of distribution of this pigment, which has already been recently widened by the unexpected discoveries of the pigment in *Paramecium*[22,23], in *Tetrahymena* (*Glaucoma*) *pyriformis*[23], and in nodules of leguminous plants[24-27]. Of special interest is the occurrence of hæmoglobin in *Neurospora* and *Penicillium*, dealt with in the following communication, especially since these moulds, like yeast (*Saccharomyces*), belong to the ascomycete fungi.

Biological significance of non-circulating hæmoglobin. The function of hæmoglobin in micro-organisms can scarcely be discussed without considering the more general problem of the biological significance of non-circulating hæmoglobin in cells and tissues of different organisms. Although this problem lies outside the scope of the present article, a few aspects of it will be briefly examined here.

There is now strong evidence in favour of the view that, at least in certain cases such as the myoglobin of red muscle[28,29] and the hæmoglobin of *Gastrophilus* larva[30], the pigment may provide a temporary store of oxygen which enables the cell to bridge over the intermittent increases in demand or decreases in supply of oxygen. However, the mode of life of micro-organisms, their small size, their high respiratory activity and the low concentration of hæmoglobin they contain preclude the possibility that their hæmoglobin may also act as a temporary store of oxygen.

The fact that the high catalytic activity of cytochrome oxidase is incompatible with the existence of a stabilized and spectroscopically visible oxygenated state of this enzyme does not by itself rule out the possibility that compounds capable of undergoing both oxygenation and oxidation may occur in Nature. Such compounds would naturally be very inefficient as either oxygen carriers or as oxidizing catalysts. In fact, no oxidizing catalyst can be obtained from hæmoglobin without abolishing its property of oxygenation. When hæmoglobin is denatured to yield a hæmochromogen it loses its characteristic property of an oxygen carrier and becomes an active oxidizing catalyst. However, under certain exceptional conditions, hæmoglobin may acquire the properties of an oxidizing catalyst without previous denaturation of the globin or separation of the latter from the catalytically active free hæm. Thus, on treating red blood corpuscles with phenylhydroxylamine, Warburg, Kubowitz and Christian[31] obtained methæmoglobin corpuscles, the oxygen uptake of which, in presence of glucose, was increased twenty-fold when compared with that of untreated corpuscles. Although the catalytic activity of methæmoglobin involves its reversible reduction to hæmoglobin, the latter, in the presence of oxygen, undergoes reoxidation to methæmoglobin instead of oxygenation to oxyhæmoglobin. According to Warburg and his co-workers, such unusual behaviour of methæmoglobin, although chemically unexplained, is of great importance for the theory of respiration. However, the study of the reactions of phenylhydroxylamine with hæmoglobin and its derivatives offered, as we have shown[32], a good chemical explanation of the phenomena observed by Warburg *et al.* Phenylhydroxylamine was found to reduce hæmatin and methæmoglobin to hæm and hæmoglobin, respectively, itself undergoing oxidation to nitrosobenzene. The nitrosobenzene then combines with hæm and hæmoglobin, forming well-defined corresponding nitrosobenzene compounds[32,33], which in the presence of oxygen undergo oxidation to free hæmatin and methæmoglobin, and in the presence of carbon monoxide give the carbon monoxide compounds of hæm and hæmoglobin. With oxyhæmoglobin phenylhydroxylamine first forms acid methæmoglobin; the reaction then proceeds further as described above. The hæmoglobin, which appears within corpuscles on the reduction of methæmoglobin by dehydrogenase systems, on combining with nitrosobenzene present in the corpuscles becomes protected from oxygenation to oxyhæmoglobin but not from reoxidation to methæmoglobin or combination with carbon monoxide[32].

Discussion of the biological significance of non-circulating hæmoglobin brings us back once more to the theory of the Japanese workers[5-6] concerning the function of the 'respiratory ferment' to which they ascribed the property of reversible oxygenation similar to that of hæmoglobin. However, it is difficult to visualize the necessity for a hæmoglobin-like component to form a link between molecular oxygen and cytochrome oxidase without making two assumptions, for which no evidence is as yet available, namely: (1) that the oxygen molecule on dissociation from an oxygenated complex has a somewhat higher oxidizing potential than ordinary molecular oxygen; and (2) that cytochrome oxidase, although autoxidizable, reacts more readily with oxygen on its liberation from such a complex than with oxygen dissolved in the surrounding medium. Were these assumptions proved correct, we should have an explanation of the possible function of intracellular non-circulating hæmoglobin, especially in cells where it cannot act as a temporary store of oxygen.

Finally, the fact that hæmoglobin may appear in very small and often variable concentrations in certain cells does not necessarily imply that it plays an active part in the respiration of these cells. Considering that most of the cells of aerobic organisms are capable of synthesizing hæmatin compounds[1], it is the availability of a suitable protein that probably governs the distribution of hæmoglobin in Nature. Since hæmoglobins of different origin may show very great variations in the chemical structure of their proteins, it is possible that within a rapidly growing cell synthesizing a great variety of proteins a suitable protein may appear which, on combining with hæm, also actively synthesized by the cell, would impart to its iron the remarkable property of combining reversibly with molecular oxygen.

Hæmoglobin in Moulds: *Neurospora crassa* and *Penicillium notatum*

SPECTROSCOPIC examination of mycelia of *Neurospora crassa* shows that the disappearance of the absorption bands of reduced cytochrome in the presence of oxygen is accompanied by the appearance of two new bands lying at about 583 and 545 mμ. Although these bands can be detected in the wild type of *Neurospora* as well as in different strains of this mould described by Mitchell, Mitchell and Tissières[1], they are more prominent in their mutant strain *C*117. The description of the compound responsible for these bands will therefore be based mainly upon the study of this strain of *Neurospora* grown in a well-aerated fluid synthetic medium[2].

Mycelium collected from a culture about five days old is washed several times in water, being each time strained and pressed out through muslin. The material thus obtained is in the form of a compact felt of mycelium which, since it is not easily aerated, shows the absorption bands of reduced cytochrome. However, the felt can be saturated with oxygen by a method previously used for the oxygenation of thick slices of muscle[3] (see also previous communication). A thick felt of mycelium is placed over the condenser of the microscope fitted with a microspectroscope ocular and compressed until it is translucent enough to show strong bands of reduced cytochrome. The mycelium is then treated with hydrogen peroxide which, on being decomposed by catalase, liberates oxygen in the form of minute bubbles which are kept imprisoned within the felt. The excess of froth is easily removed by slightly compressing the felt with a spatula. Under these conditions it can be seen that the absorption bands of reduced cytochrome rapidly disappear and are replaced by two new bands : α- 583 mμ and β- 545 mμ. As the oxygen is used up, these two bands gradually fade while the bands of reduced cytochrome reappear. Partial oxygenation of the mycelium, without the use of hydrogen peroxide, is obtained when a thick felt of mycelium is quickly compressed and released. Cytochrome bands may then be seen to decrease in intensity, and sometimes even to disappear, while the bands at 583 and 545 mμ reappear. However, within a few seconds the absorption spectrum reverts to the original state, showing only the bands of reduced cytochrome.

All further work on the compound responsible for the bands at 583 and 545 mμ was carried out upon cell-free preparations which were obtained by grinding the mycelium in a cold mortar with 0·5 parts of sand and 0·3–1 part of water and centrifuging off the solid residue which carries with it most of the cytochrome. The supernatant fluid was further clarified by high-speed centrifugation (15,000–20,000*g*) for a period of one to two hours in a refrigerated centrifuge to give an opalescent orange-yellow solution, which on aeration shows the same two distinct absorption bands at 583 and 545 mμ. If this solution is left standing at room temperature these bands gradually disappear and, within twenty to sixty minutes, are replaced by very feeble bands of the reduced components of cytochrome which are probably associated with insoluble material still present in the solution and responsible for its opalescence. On passing air through this solution the bands of cytochrome are replaced by the bands at 583 and 545 mμ, which rapidly disappear on treating the solution with sodium dithionite ($Na_2S_2O_4$) or on bubbling pure nitrogen through it. In both cases they are replaced by weak bands of reduced cytochrome.

On passing through the solution a current of a gas mixture composed of carbon monoxide and oxygen ($CO/O_2 = 4$) the bands at 583 and 545 mμ are replaced by two bands at 574 and 539 mμ ; the original bands reappear, however, when the solution is vigorously aerated. Finally, the two bands (583 and 545 mμ) also disappear when the solution is treated with potassium ferricyanide but without being replaced by any detectable bands in the visible region of the spectrum.

The facts that the new absorption bands at 583 and 545 mμ appear when the solution is aerated and disappear when it is deprived of oxygen or treated with potassium ferricyanide and are replaced in presence of carbon monoxide by two diffuse bands at about 574 and 539 mμ indicate that these bands belong to an oxygenated ferrous hæmoprotein such as oxyhæmoglobin or oxymyoglobin. This pigment appears in the mycelium on the third day of cultivation, reaches its maximum concentration on the fifth day and then gradually disappears.

The concentration of oxyhæmoglobin in intact fresh five-days old mycelium is of the same order of magnitude as that of some components of cytochrome. In the opalescent cell-free extract of mycelium its concentration can be determined precisely by matching the absorption spectrum of a well-aerated extract with that of a standard solution of oxymyoglobin. The estimation is carried out with a microspectroscope outfit provided with a double wedge trough[4]. The total hæmatin content of the extract can be similarly estimated by transforming all the hæmoproteins it contains into pyridine hæmochromogen, the absorption spectrum of which is matched with a standard solution of pyridine hæmochromogen prepared from pure hæmin. Assuming that the equivalent weight of hæmoglobin of *Neurospora* is about the same as that of mammalian hæmoglobin or myoglobin, namely, 17,000, the extract of *Neurospora* was found to contain about 10 mgm. per cent of hæmoglobin. The total hæmatin content of this extract estimated as pyridine hæmochromogen was, however, higher than could be accounted for by the hæmoglobin and the residual cytochrome. In fact, the hæm of hæmoglobin represented only about 60 per cent of the total hæm present in the extract. The main part of the non-hæmoglobin hæm appears to be in the form of free hæm which is derived, as will be shown presently, from hæmoglobin as well as from some of the components of cytochrome.

Of other moulds we have so far only made a systematic study of *Penicillium notatum*, which was cultivated and harvested in the same way as *Neurospora* to give a compact felt-like mass of mycelium. When examined with a microspectroscope it shows strong absorption bands typical of reduced cytochrome. On rapid compression and release of the felt or on treating it with hydrogen peroxide, the absorption bands of reduced cytochrome disappear and are replaced by the bands at 583 and 545 mμ, although the second band is not always visible. The absorption band at 583 mμ can also be seen in mycelium resuspended in water and vigorously aerated. The fact that this band appears on oxygenation, disappears on deoxygenation or on treating the suspension with quinone, and is shifted to 574 mμ in presence of carbon monoxide, shows that it belongs to an oxygenated ferrous hæmoprotein or oxyhæmoglobin. Unfortunately, the attempts to obtain a hæmoglobin-containing clarified extract of *Penicillium* were unsuccessful, since most of the hæmoglobin in the crude extract was either enzymically destroyed or attached to the insoluble fraction.

One of the important conditions for the study of hæmoglobin and the cytochromes of moulds is that it must be carried out upon material freshly obtained and that only submerged and properly aerated mycelium should be collected and not the mycelium which, owing to vigorous aeration, may have been projected out of the medium and be found attached to the walls of the vessels above the level of the fluid. In fact, mycelium which remains outside the aerated nutrient medium even at low temperatures (+ 2° C.) undergoes autolysis accompanied by very marked changes in its absorption spectrum. The absorption bands both of hæmoglobin and the cytochromes (except cytochrome *c* of *Penicillium*) gradually diminish in intensity, while two somewhat diffuse but strong bands appear at about 587 and 548 mμ. Although these absorption bands lie very near those of oxyhæmoglobin, spectroscopic study of moulds or their extracts under different conditions has revealed that the bands belong to free protohæm (ferroprotoporphyrin). The evidence in support of this view can be summarized as follows: (1) they show great similarity to the absorption bands of hæm which are obtained on reducing an alkaline solution of hæmin with sodium dithionite ($Na_2S_2O_4$); (2) on aeration these bands disappear and very slowly reappear when aeration is stopped; (3) they are intensified on treating the mould or its extract with a reducing agent ($Na_2S_2O_4$); (4) in the presence of carbon monoxide they are replaced by much stronger bands lying at about 567 and 537 mμ; (5) on addition of imidazole these bands are replaced by the very strong bands of imidazole hæmochromogen. This reaction is of special interest since hæmoglobin, oxyhæmoglobin and the components of cytochrome do not react with imidazole.

There is very little doubt that the free hæm which appears in moulds originates from hæmoglobin and some of the components of cytochrome by an enzymic degradation of these hæmoproteins which accompanies the autolysis of the mycelium. It is somewhat surprising that the hæm does not appear to combine with some of the nitrogenous substances or denatured proteins present in the mycelium to form hæmochromogens. It follows that either no suitable substances are available to react with the hæm or that the conditions are not favourable for such a reaction to take place. However, in some specimens of moulds the intensification of the absorption bands of hæm and their displacement towards the blue end of the spectrum (to 576 and 537 mμ) indicate the possibility of a complex formation between a protein and the hæm whereby only the porphyrin of the hæm is linked to the protein. Such complexes would resemble the hæm–albumin compound.

In old mycelia the free hæm itself undergoes a further degradation which consists in the liberation of iron and the appearance of free porphyrin, which can easily be recognized on direct spectroscopic examination of the mycelium or of an extract obtained by treating it with a mixture of ether and glacial acetic acid. All these changes are more marked and develop more rapidly in the mycelium of *Penicillium* than in that of *Neurospora*.

In some samples of moulds these degradation products may even be detected during growth and proliferation of the mycelia. Owing to their distinctive properties, however, their presence does not interfere with the study of the unchanged hæmoproteins such as hæmoglobin and the components of cytochrome.

This work forms part of the general study of cellular biology supported by the Nuffield Foundation.

Isolation of Penicillaminic Acid and D-α-Aminoadipic Acid from Cephalosporin *N*

CEPHALOSPORIN *N*, an antibiotic produced by a species of *Cephalosporium*, was recently reported to be a new type of penicillin. The physical properties of this substance indicated that it contained a basic group as well as acidic groups[1]. The purest preparation of cephalosporin *N* so far obtained, which appears from analysis of a counter-current distribution curve to be at least 50 per cent homogeneous, has now been found to yield D-α-aminoadipic acid on hydrolysis. While L-α-aminoadipic acid is known to occur in Nature[2,3], the D-isomer does not appear to have been isolated previously from a natural source.

The preparation of cephalosporin *N* was hydrolysed in *N* hydrochloric acid at 100° for six hours, and the hydrolysate was separated by electrophoresis into neutral and acidic fractions.

The neutral fraction was oxidized with bromine water and the acidic material formed was again separated by electrophoresis. On treatment with charcoal and crystallization from aqueous acetone this material yielded colourless prisms of penicillaminic acid (ββ-dimethylcysteic acid) (found: C, 30·6; H, 6·0; N, 6·9 per cent; $C_5H_{11}O_5NS$ requires: C, 30·7; H, 5·6; N, 7·1 per cent).

The acidic fraction contained an amino-acid which behaved on two-dimensional paper chromatograms like α-aminoadipic acid. This amino-acid was obtained in a homogeneous state by chromatography on a column of 'Amberlite *XE*-59', eluting with 0·2 *M* ammonium acetate buffer, *p*H 5[4]. It crystallized from water, melting point 205–207°, $[\alpha]^{20}_{D} = -26°$ ($c = 1$ in 6 *N* HCl) (found: C, 44·2; H, 7·0; N, 9·0; $C_6H_{11}O_4N$ requires: C, 44·7; H, 6·9; N, 8·7).

This substance showed no depression in melting point on mixing with a sample of authentic D-α-aminoadipic acid. Electrometric titration showed the presence of two acidic groups of *pK* 2·2 and 4·4 respectively and a basic group of *pK* 9·8. An X-ray powder photograph was kindly taken by Dr. D. Hodgkin, who reported that it was identical with a photograph of authentic D-α-aminoadipic acid. Oxidation with chloramine-*T*[5] and addition of 2 : 4-dinitrophenyl hydrazine to the resulting solution yielded an acidic 2 : 4-dinitrophenylhydrazone, melting point 130–131°, which appeared to be derived from γ-aldehydo-*n*-butyric acid (found: C, 44·8; H, 4·2; N, 18·4 per cent; $C_{11}H_{12}O_6N_4$ requires C, 44·5; H, 4·7; N, 18·9 per cent). The same compound was formed on oxidation of DL-α-aminoadipic acid.

The preparation of cephalosporin *N* contains a basic group of *pK* 9·8 and forms a dinitrophenyl derivative with fluorodinitrobenzene. This derivative yields a compound on hydrolysis which behaves like DNP-α-aminoadipic acid on paper chromatograms. It is therefore concluded that the α-amino group of α-aminoadipic acid is free in the active material. Since the *pK* values of the basic group in this material and in the amino-acid are very similar, it appears likely that α-aminoadipic acid is linked to the rest of the molecule through its δ-carboxyl group.

The evidence so far available is not incompatible with the assumption that cephalosporin *N* is an α-aminoadipyl derivative of the essential core of the penicillin molecule. A compound of this structure would be expected to have the physical properties of the antibiotic. The existence of glutamyl and aspartyl derivatives is also possible. Traces of glutamic acid and aspartic acid were liberated from the purest preparation of cephalosporin *N* on hydrolysis with *N* hydrochloric acid at 100°, and larger amounts from cruder preparations.

The presence of a free amino group obviously makes it possible to prepare derivatives of cephalosporin *N* by reactions which cannot be applied to benzylpenicillin. It is of interest that the DNP-derivative, which, unlike the parent substance, can be extracted into ether or ethyl acetate, has a higher activity than the latter against *Staph. aureus* and a much lower activity against *Salm. typhi*.

We are indebted to Dr. J. P. Greenstein for a sample of synthetic D-α-aminoadipic acid, to Dr. Borsook for a sample of L-α-aminoadipic acid, and to Drs. Fones, Gaudry and Work for samples of DL-α-aminoadipic acid.

A Colorimetric Method, based on Metallic Complex Formation, for the Detection of Aureomycin in Presence of Amino-Acids and Proteins

EXPERIMENTS involving the feeding of aureomycin to animals are now so common that it would be an advantage to have a rapid and reliable chemical method for its detection in body fluids and similar media. This is the more desirable since microbiological methods of assay are not easy to carry out because of the instability of the antibiotic in ordinary bacteriological media, even at 25° [1,2]. There is one remarkable chemical property of aureomycin, apparently not yet recorded in the literature, which might be made use of to this end, namely, its ability in alkaline solution to form stable, yellow complexes, soluble in *n*-butanol, with certain divalent cations only, notably Mg, Ca, Co, Ni, Cu and Sr. Zn, Cd, Mn, Ba, Hg and Pb do not form stable coloured complexes. Aureomycin alone gives, of course, a yellow colour with excess of ammonia or caustic soda, but this fades quite quickly and irreversibly at 30°, a purple fluorescence developing in its place. Shaking with *n*-butanol then extracts no colour.

Many divalent cations also form stable complexes with amino-acids[3], and hence their colours (if any) with aureomycin may not be stable in bacteriological media. It happens, however, that the affinity of aureomycin for Ca^{++} and Co^{++} is so great that this limitation is scarcely felt with these cations. Thus, to demonstrate the calcium or cobalt colours in presence of other divalent cations, the following final concentrations (μgm./ml.) are suitable: pure aureomycin hydrochloride, 200–400; 'Bactogelatine' (calcium-free), 1,000; Ca^{++} or Co^{++}, 20–40. Ammonia or sodium hydroxide is added last of all to a final concentration of about 0·25 or 0·04 *M* respectively. The mixture is kept at 30° for 90 min. and then shaken with enough *n*-butanol to give a distinct top layer. A yellow colour in the top layer only denotes calcium; in both layers, cobalt. The 'Bactogelatine' in conjunction with ammonia will suppress the colours otherwise given by Mg^{++}, Cu^{++} or Ni^{++}; in conjunction with sodium hydroxide it will also suppress the colour due to Sr^{++}. It has practically no effect, however, even after several hours standing, on the colours given by Ca^{++} or Co^{++}. The cobalt colour is much browner than the calcium colour, which is a pure yellow.

For the detection of aureomycin, calcium is the metal of choice since its complex is completely extracted from aqueous solution by one shaking with *n*-butanol. (The $CaCl_2$ complex of the structurally related antibiotic terramycin has already been described by Regna *et al.*[5].) It is quite easy to detect 20 μgm./ml. of aureomycin in a solution containing both 'Bactogelatine' (0·1 per cent) and 'artificial' casein hydrolysate (0·1 per cent, made according to the directions of Norén[4]) by adding a drop or two of 0·2 per cent calcium chloride solution, using sodium hydroxide as the alkali rather than ammonia, and incubating at 30° for 15 min. only. An aureomycin control without calcium chloride and a calcium control without aureomycin give absolutely no colour in the top layer. Such a solution corresponds to a bacteriological medium. Alternatively, one may use 1 per cent peptone water which, however, usually contains enough calcium already to give the test when aureomycin is added.

It should be mentioned that the calcium-free 'Bactogelatine' ('Difco') specimen here used was *sui generis*. All other specimens of bacteriological gelatin by other suppliers seemed to contain calcium. Likewise, two commercial specimens of acid hydrolysed casein also contained enough calcium to give the test. On the other hand, among scores of commercial specimens of amino-acids only *two*—one out of several of methionine and one of cysteine hydrochloride—gave the test in absence of added calcium chloride, and so it was possible to make up a calcium-free 'artificial' casein hydrolysate to simulate a bacteriological medium.

In addition, aureomycin may be used as a reagent for detecting traces of calcium in presence of magnesium and of cobalt in presence of nickel, and may thus be of some use in analytical chemistry.

I am indebted to Dr. A. T. Mennie, medical director, Lederle Laboratories Division, Cyanamid Products, Ltd., Bush House, London, W.C.2, for arranging for a supply of pure aureomycin hydrochloride to be sent to this Institute for calf-feeding experiments.

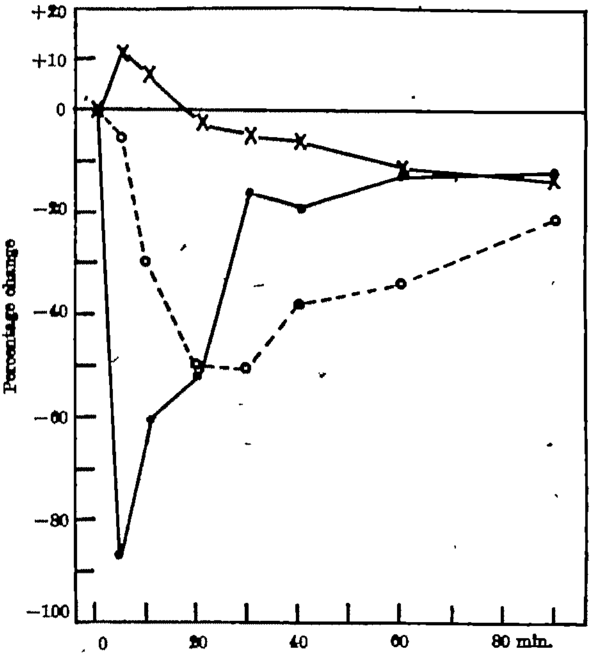
Effect of Insulin on the Adrenergic Amines of Blood

IT is generally assumed that the stimulation of adrenalin secretion which is observed after insulin administration is a reaction not caused by insulin itself but by the hypoglycæmia which it produces. It has also often been claimed, with and without supporting evidence, that insulin hypoglycæmia is accompanied by hyperadrenalinæmia. This claim is not correct, as has recently been shown[1]. The intravenous injection of insulin in fasting subjects leads to an immediate and pronounced drop of the level of adrenergic amines in plasma which precedes the fall of the blood sugar. Likewise, in the recovery period, the return of the level of adrenergic amines to the norm precedes the rise of the blood sugar curve. If coma doses of insulin are injected the plasma-level of adrenergic amines remains depressed, until the coma is terminated by glucose administration. The effect of insulin is also observed, although in mild and modified form, if the development of hypoglycæmia is prevented by a preceding glucose ingestion.

The method which was used in these studies did not permit a differentiation between adrenalin and noradrenalin, but a modification has recently been developed[3] with which this has become possible. Its application to the insulin effect has shown that the drop is entirely or almost entirely accounted for by the disappearance of adrenalin from plasma. The level of noradrenalin remains stationary or is, in some cases, slightly reduced. A typical result is shown in the accompanying figure. The concentration of adrenalin and noradrenalin in red blood cells is unchanged or diminished.



Percentage changes of the concentrations of adrenalin, noradrenalin and glucose in plasma after the intravenous injection of insulin (0·1 unit/kgm.).

●——●: adrenalin concentration changes; initial concentration 1·56 μgm./litre of whole blood. ×——×: noradrenalin concentration changes; initial concentration 5·68 μgm./litre of whole blood. ○- - - -○: glucose concentration changes; initial concentration 75·6 mgm. per cent

It must be assumed, therefore, that under the influence of insulin the fixation of adrenalin in the tissues is increased, and this has been clearly demonstrated by Hökfelt[3]. The increased secretion of adrenalin after insulin administration may thus be a reaction to compensate for the lowering of the plasma adrenalin-level, rather than an effect of hypoglycæmia. Euler and Luft[4] have recently shown that insulin causes an increased urinary excretion of adrenalin, but not of noradrenalin. This observation would be difficult to reconcile with the reduction of plasma adrenalin-levels, unless it is assumed that the adrenergic amines of urine exist largely in the conjugated form. The conjugated amines would not be estimated by the method used for the analysis of blood.

Extremely High Alkaline Phosphatase Activity in the Vaginal Mucus of the Cow

In the course of an investigation on the phosphatase content of the vaginal smear of some non-pregnant cows and heifers, extremely high alkaline phosphatase activity was observed in the mucus at regular intervals corresponding with the ovarian cycle of the animal. The highest values were found on the day that mucus secretion begins, two days before the visible signs of heat (bellowing, unrest, willingness to copulate). On that day a relatively small but highly active amount of mucus is secreted. A second period of relatively high activity of the mucus is often seen between the eighth and the twelfth day *post œstrum*. The activity is rather variable in different individuals and the daily variations may be great, especially in periods of irregular mucus secretion.

The diagram indicates the concentration of alkaline phosphatase in the mucus of a normal, healthy cow. Phosphatase activity is expressed in King and Armstrong units[1] per 100 gm. of mucus. In our first series of experiments, the mucus was homogenized and dissolved in water; later, we used a 0·06 per cent magnesium chloride solution in order to obtain maximal activation. Since the amount of mucus which was secreted daily could not be estimated, the diagram does not give the total amount of phosphatase produced. During œstrum, mucus secretion is abundant, but the clear mucus is only slightly active.

Alkaline Phosphatase Activity (King and Armstrong Units per 100 gm.) in the Vaginal Mucus of Heifers

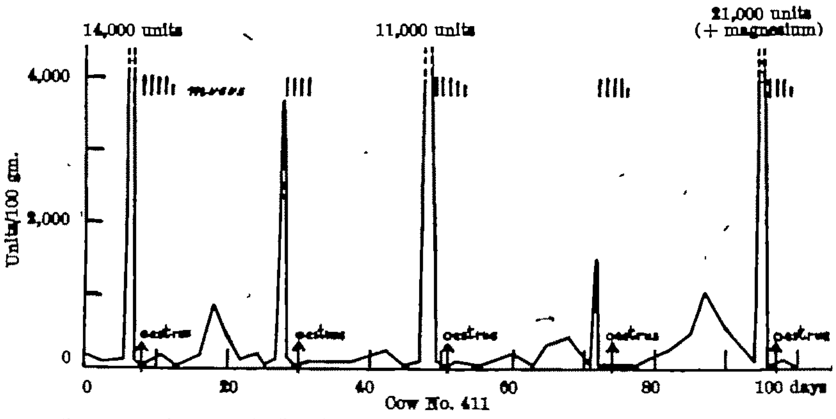
Date	21/4/52	23/4/52	28/4/52	1/5/52	4/5/52
No. 817	27,600	100*	100	86	—
„ 818	3,200	1,890	11,040	5,180	460
„ 819	1,040	220	200	104	290
„ 820	6,000	26,200	100*	610	3,000
„ 821	7,500	3,310	1,520	510	800
„ 822	9,500	1,240	320	760	700

* = œstrum.

Days of abundant secretion are indicated in the diagrams by vertical lines. The rapid fall in activity just before œstrum is an effect of dilution and cannot be ascribed to instability of the enzyme, since a sample of highly active mucus (14,000 King and Armstrong units per 100 gm.) retained its full activity while stored at room temperature for three days.

Large amounts of alkaline phosphatase are secreted by heifers, especially in the period of first œstrum. A characteristic picture of the very high and variable activities found in the mucus of six heifers is given in the accompanying table.

The alkaline phosphatase diagram probably gives a picture of the permeability of the vaginal epithelium and of the amount of enzyme stored in the mucosa. The influence of castration, hormones and diet (feeding of phosphates) is now under investigation. In a case of corpus luteum persistens, very low alkaline phosphatase values were found. Stable dry enzyme preparations, containing 50–100 per cent of the original activity, can be obtained from the mucus by precipitation with cold ethanol or acetone. Our most active preparations, 40–50 King and Armstrong units per mgm. nitrogen, showed a positive biuret, a strong Molisch and a negative phosphorus reaction.



Alkaline phosphatase activity (in King and Armstrong units per 100 gm.) in the vaginal mucus of a cow during five ovarian cycles. Days of abundant mucus secretion are indicated by short vertical lines; days on which full œstrus was observed are marked by an arrow

I am grateful to Dr. J. I. Terpstra, at whose instigation this study was undertaken, and to Mr. W. A. Eisma and Miss M. E. Goedkoop for veterinary and technical assistance.

Isolation of a Mixed Disulphide of Glutathione and Cysteinylglycine from a Partial Hydrolysate of Glutathione

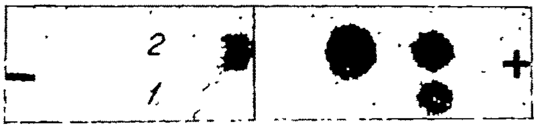
Glutathione, γ-glutamylcysteinylglycine, can easily be split into glutamic acid and cysteinylglycine by mild acid hydrolysis[1], and even without acid by heating in a water solution[2]. The tripeptide has therefore been used as material for the preparation of cysteinylglycine. In order to prepare this dipeptide for a microbiological purpose, the latter of the two methods was tried.

Glutathione, dissolved in distilled water, was hydrolysed for five days at 62° C. The cysteinylglycine and possibly unhydrolysed glutathione were precipitated as their mercaptides with mercuric sulphate. The precipitate was washed with water and decomposed with gaseous hydrogen disulphide. The mercuric sulphide was removed by centrifugation and the supernatant neutralized with barium hydroxide. After evaporation of the solution to a few millilitres, precipitation was made with absolute alcohol. During storage the SH-groups originally present were oxidized (test with sodium nitroprusside). In order to examine whether the hydrolysis was complete, a one-dimensional descending chromatogram was developed in the usual manner with acetic acid : *n*-butanol : water (1 : 4 : 5) and Whatman No. 1 paper. More than one component was detected, but the resolution of the mixture was unsatisfactory, and therefore electrophoresis on paper was tried according to the method of Kunkel and Tiselius[3]. The run was made in acetate buffer (pH 4·5, μ 0·05) with about 0·2 mgm. of the substance on Munktell 20 paper and using a potential gradient of 5 V./cm. for six hours. The position of the material was determined by treating the paper with ninhydrin solution. As seen from the illustration (row No. 2), three spots could be detected on heating the paper, two of which (*B* and *C*) travelled towards the anode, while the third (*A*) was immobile. Spot *C* was found to be oxidized glutathione, since this substance gave an identical spot (row No. 1 in the illustration). Judging from its yellowish colour and position, spot *A* was cystinyl-*bis*glycine, and this was confirmed by paper chromatography.

Spot *B* was eluted from a paper run in the same way as above, its position being determined with ninhydrin on a narrow strip of the paper. After hydrolysis of the component in 6*N* hydrochloric acid at 110° C. overnight, a paper chromatogram revealed the presence of the same amino-acids as in glutathione. Since no SH-groups were present, the component must be a disulphide. It was therefore oxidized with performic acid[4] and chromatographed on Whatman No. 1 paper with acetic acid : *n*-butanol : water (1 : 4 : 5). Two spots were detected, the faster one being $(CySO_3H).Gly$ and the slower one, γ-Glu.$(CySO_3H).Gly$, the sulphonic acid derived from glutathione. Synthetic samples of these peptides were used as references. The unknown compound was thus a mixed disulphide of glutathione and cysteinylglycine,

$$\begin{array}{c}\gamma\text{-Glu.(CyS).Gly}\\ | \\ \text{(CyS).Gly.}\end{array}$$

Since both the glutathione and the cysteinylglycine had been isolated in their reduced forms from the hydrolysis mixture, this mixed disulphide must in this case have been formed secondarily by oxidative coupling of the peptides during storage. It might also be formed as an intermediate product in the hydrolysis of oxidized glutathione. A similar mixed disulphide has also been prepared from glutathione and cystein by oxidation with perhydrol at pH 7·5. It could be separated from the reaction mixture in the same way as above.



Electrophoresis on paper of a partial hydrolysate of glutathione: (1) oxidized glutathione; (2) partial hydrolysate of glutathione

Enzymatic Hydrolysis of Urinary Neutral 17-Ketosteroid Conjugates

It is generally accepted that urinary steroids are excreted almost entirely in the form of water-soluble conjugates with glucuronic and sulphuric acids. Acid hydrolysis has been extensively used to liberate free steroids from these conjugates; but the conditions necessary for complete hydrolysis are such that considerable changes occur within the steroid molecules themselves, particularly the substitution of the hydroxyl group of androst-5-en-3-β-ol-17-one (dehydroisoandrosterone) by chlorine.

β-Glucuronidase preparations have been shown to split steroid glucuronides and have been applied to the hydrolysis of corticosteroid, œstrogen and ketosteroid conjugates. The application of sulphatase concentrates has been mainly confined to the liberation of the phenolic œstrogens from their sulphates; the sulphatases of microbiological origin have been shown to be ineffective for hydrolysing the neutral 17-ketosteroid conjugates[1]. Henry and Thevenet[2] and Henry, Thevenet and Jarrige[3] have, however, recently described the total hydrolysis of urinary steroid conjugates and the hydrolysis of the potassium salt of androst-5-en-3-β-ol-17-one sulphate with sulphatase and β-glucuronidase preparations from the edible snail (*Helix pomatia*).

The recently published work of Dodgson and Spencer[4] has shown the high β-glucuronidase and phenol sulphatase activity of extracts of the visceral hump of the common limpet (*Patella vulgata*). We have found that an extract of the visceral hump of this species of mollusc hydrolysed a sufficiently large amount of the neutral 17-ketosteroid conjugates present in urine to indicate that a steroid alcohol sulphatase was active. The extract was prepared from acetone-dried visceral hump by extraction with 0·1 *N* potassium chloride at pH 8·0, precipitation by half saturation with ammonium sulphate, followed by dialysis and freeze-drying of the precipitate.

This extract, when incubated with normal male urine at pH 5·0 for periods up to 96 hr., released amounts of 17-ketosteroids exceeding 90 per cent of

Table 1. Release of 17-Ketosteroid-like Substances from a Normal Male Urine by Acid Hydrolysis and Enzymatic Hydrolysis

Volume of urine (ml.)	Treatment	17-Ketosteroids released (crude totals in μgm.)
25	Acid hydrolysis	173
	Enzymatic hydrolysis (50 mgm.* enzyme concentrate at pH 5·0, 37° C.)	
25	(a) Incubated for 24 hr.	92
25	(b) Incubated for 77 hr.	167
25	Urine incubated at pH 5·0 and 37° C. for 77 hr. without enzyme	6

Table 2. Enzymatic Hydrolysis of the Sodium Salt of Androst-5-en-3-β-ol-17-one Sulphate

Substrate	Treatment	17-Ketosteroid released	
		Crude total (μgm.)	Per cent
Sodium salt of androst-5-en-3-β-ol-17-one (80 μgm./ml.)	2 hr. at pH 4·8, 37° C. Blank	3	0·75
"	1 hr. at pH 4·8, 37° C. + enzyme (10 mgm.*)	38	9·5
"	2 hr. at pH 4·8, 37° C. + enzyme (10 mgm.*)	77	19·2

* The alcohol sulphatase activity of the enzyme preparation was estimated by measuring the rate of release of androst-5-en-3-β-ol-17-one from the sodium salt of androst-5-en-3-β-ol-17-one sulphate, and will be described in detail elsewhere.

that obtained by acid hydrolysis performed according to the method of Callow. Table 1 gives the detailed results of a typical experiment. Moreover, the extracts so obtained were considerably less contaminated by urinary chromogens than after acid hydrolysis.

Fractionation by partition chromatography[5] of the urinary steroid complex liberated by enzyme action showed a marked absence of the 'artefact' peak, particularly 3-β-chloroandrost-5-en-17-one. The peak corresponding to androstan-3-α-ol-17-one (androsterone) was obtained in similar yield by both enzymatic and acid hydrolysis of aliquots of the same urine.

The same extracts of *P. vulgata* have been shown to contain a β-glucuronidase by estimation of the rate of liberation of glucuronic acid from borneol glucuronide. An optimum value of *p*H 4·0 was observed for this reaction. Similarly, these extracts were shown to hydrolyse the pure sodium salt of androst-5-en-3-β-ol-17-one sulphate (Table 2), the liberated free ketosteroid being estimated by means of the Zimmermann reaction. The optimum *p*H for this reaction was in the region of 4·8–5·0.

Differences between the rates of enzymatic hydrolysis of urinary steroid conjugates and those obtained using pure substrates pointed to an inhibition by urinary constituents. A private communication from Drs. Dodgson and Spencer (in the press) directed our attention to their work on the inhibition of the phenol sulphatase from *P. vulgata* by urine, in which they showed that both sulphate and phosphate ions inhibit the reaction of their enzyme. We have found that removal of sulphate and phosphate ions from the urine, as they suggest, considerably increased the rate of hydrolysis of urinary neutral 17-ketosteroid conjugates.

Further details of this work will be published elsewhere.

Potential Constants of Diacetylene

A misinterpretation of the vibrational spectrum of diacetylene ($HC\equiv C—C\equiv CH$)[1] led to very low values of the potential (force) constant corresponding to the central carbon–carbon bond. Although some justification was offered for this low value[2,3] the recent experimental work of Jones[4] and a correlation study of diacetylene and similar molecules[5] led to the conclusion that the previous assignment of the fundamental frequencies and, therefore, the potential constants obtained from them, must be discarded. Several recent publications[1,4,6] agree in giving a value for the central carbon–carbon bond-stretching potential constant which is substantially higher than the value corresponding to a single bond.

A normal co-ordinate treatment has now been carried out for diacetylene by using the frequencies given by Jones[4], without transferring any potential constant from similar molecules. Different sets of constants were obtained, corresponding to values of the C—H potential constant in a range close to the corresponding value in acetylene. The value of the central-bond potential constant has been established in this way between 6·6 and 6·8 md./A. Coulson and Longuet-Higgins[7] have given expressions for the stretching-potential constant of a bond in conjugated hydrocarbons; and Coulson[8] has also plotted curves relating the mobile bond-order to the atomic radius of carbon for different values of the coefficient of orbital mixing. In diacetylene, where the σ-bond is of *sp* type, the bond order is 0·70, corresponding to a radius of 0·68 A. If we use a value of 6·7 md./A. for the potential constant, the corresponding self-polarizability is $-2\cdot 20$ (md./A.)$^{-1}$, which is definitely smaller (in absolute value) than it would have to be to justify a drastically low value of the potential constant, as reported previously. Recently, Longuet-Higgins and Burkitt[9] have calculated a potential constant of 7·97 md./A., in qualitative agreement with our results, although, in terms of the present normal co-ordinate treatment, the latter figure for the potential constant seems too high. It does not seem possible that the neglect of the anharmonicities and very small interaction constants may produce such a large difference.

Coulson and Longuet-Higgins[8] have pointed out the great difficulties involved in the theoretical calculation of mobile bond-orders and bond polarizabilities. The method used here may provide an independent check for such calculations. A more detailed account of the work outlined above will be published in the *Journal of Chemical Physics*.

Effect of Thyroxine on Coenzyme *A* Levels

Attempts to establish the mechanism and site of action of thyroxine upon peripheral tissues have occupied the interest of a number of investigators, and a detailed account of the various areas of study has been presented in Barker's[1] review. Of the various possibilities suggested, it may be mentioned that thyroxine has been stated to cause a release of co-enzymes, protein carriers or other substances needed for many of the energy-transforming processes in cells[2,3]; but neither the mechanism of release nor the source of these materials is clear. Martius and Hess[4] have suggested that thyroxine acts as an uncoupling agent.

In investigating the peripheral action of thyroxine it would appear logical to study a system which has been demonstrated to exert an influence upon the basic economy of the body. Recent developments in the establishment of the function of coenzyme *A* have demonstrated the fact that a number of reactions which previously had been shown to be influenced by the thyroid state are coenzyme *A*-dependent. This suggests that there may be a relationship between coenzyme *A* and thyroxine.

With these considerations in mind, it was decided to determine what influence, if any, the thyroid exerted upon the coenzyme *A*-levels in liver, heart, brain and intestine. The experimental animals used were white male Wistar rats of approximately 90–150 gm. weight. Ten of these animals were thyroidectomized with iodine-131 and then after an appropriate interval separated into two groups: *A*, controls; and *B*, animals treated with 150 μgm. of sodium L-thyroxine pentahydrate per 100 gm. body weight. All animals were killed two days following the injection of thyroxine, and the coenzyme *A* concentration determined in the various tissues by the Kaplan–Lipmann[5] procedure. (The coenzyme standard was supplied by Dr. F. Lipmann.)

The results are presented as per cent increase of the coenzyme *A* level in the treated group over that found in the control thyroidectomized group.

Coenzyme *A* Units per gm. Fresh Tissue

	Liver	Heart	Brain	Intestine
Group *A*	49	18	9	7
Group *B*	121	25	12	10
Per cent increase of treated group	147	39	33	43

These results suggest that further studies of a more detailed nature into the relationship of coenzyme *A* and thyroxine should be made. If it is true that thyroxine acts by influencing the concentration of this coenzyme in tissues, a significant step will have been made towards understanding the action of thyroxine. In a collateral study it has been demonstrated that triiodothyronine in doses 1/5 those of thyroxine used above had substantially the same effect upon coenzyme *A* tissue levels[6].

A more detailed report of this work will be published elsewhere.

Synthesis of Components of the Vitamin B Group by *Corynebacterium diphtheriae*

In the course of a more extensive study concerning the metabolism of *C. diphtheriae*, it was found necessary to estimate to what extent vitamins of the B group, known to function as co-enzymes for various desmolases, appear in the medium during the growth of the bacterium. Previously, the occurrence of pantothenic acid, thiamine and riboflavine in the culture filtrates of the diphtheria bacterium, grown on semi-synthetic media, has been strongly indicated[1]. On examining this further, the following additional vitamins (or substances with similar activity in microbiological assays) were found to be synthetized by *C. diphtheriae*: vitamin B_6 complex, biotin, *p*-aminobenzoic acid, folic acid and vitamin B_{12}.

The assays were made from the routine medium and culture filtrate (crude toxin) used for the production of diphtheria prophylactic in this laboratory. This substrate is a modification of the low-nitrogen casein hydrolysate medium proposed by Holt[2]. It has a very low initial content of growth factors, except those included in the added essential nutrients of Mueller[3] (β-alanine, nicotinic acid, pimelic acid, cystine and the inorganic elements). The sodium chloride content of the medium is 0·5 per cent, and the nitrogen content is brought to 0·11 per cent by adding glycine and glutamic acid (1 : 1). Instead of the usual ferrous sulphate solution for the adjustment of the iron-level of the medium, a solution of yeast autolysate is used as a source of iron[4]. The yeast autolysate obviously contains, besides iron, some additional important factors, and thus a more regular and higher toxin production is guaranteed (usually 120–150 *Lf* doses per ml. in cultures incubated for five days at 34° C.—the initial purity of the toxin being greater than 1,000 *Lf* doses per mgm. protein nitrogen). One of the effective agents in the autolysate seems in all probability to be thiamine[5]; another is possibly inositol. The amount of yeast autolysate added to the medium is so small

* Obtained through the courtesy of Dr. Paul R. Burkholder, Yale University, Connecticut.

† Another 'Toronto'-variant of *C. diphtheriae* producing an anomalous toxin on a medium with very high yeast autolysate content (ref. 13) was found capable of synthetizing more than 50 mγ/ml. of vitamin B_{12} in the culture filtrate.

that only riboflavine, biotin, inositol, thiamine and, of course, nicotinic acid can be detected in it in significant amounts. The strain of *C. diphtheriae* used in this investigation was a 'Toronto'-variant labelled *CN* 2000, which was obtained from the Wellcome Research Laboratories, Beckenham, England, through the courtesy of Dr. F. V. Linggood.

In the analysis of the medium and the culture filtrate, the techniques used were exclusively those of microbiological vitamin assay. In the case of vitamin B_{12}, the identity of the active compound with vitamin B_{12} was ascertained paper-chromatographically[4]. The results are given in the accompanying table.

The figures given are extreme values from several assays from different batches of the medium and toxin (culture filtrate). The symbols ±, + and ++ are used when the activity of the tested compound in the sample was too slight to be estimated with sufficient accuracy, even when undiluted medium or toxin was assayed. In the case of thiamine it was, however, possible to observe that the toxin always had a clearly weaker thiamine activity than the corresponding medium. Thus it seems evident that this strain of *C. diphtheriae* does not secrete thiamine into the growth medium. If thiamine is synthetized, it is retained in the bacterial cell.

Of the other compounds investigated, nicotinic acid and inositol are largely drawn from the substrate, inositol almost quantitatively. Riboflavine, pantothenic acid, vitamin B_6 complex, biotin, *p*-aminobenzoic acid, folic acid and vitamin B_{12} are synthetized and appear in the toxin in considerable amounts.

This investigation was aided by a grant from the Sigrid Juselius Foundation.

Some Interrelationships of the Erythrocytes of Various Species with Plant Agglutinins

EARLY studies by Landsteiner[1] indicated that while plant agglutinins acted upon the red cells of most species, specificity could be considered to exist if the action of a given plant extract against a limited series of cells was considered. For example, lentil extracts agglutinated rabbit's red cells but not pigeon's red cells. Recent experiments[2] revealed that extracts of common strains of *Dolichos biflorus* agglutinated human *A* cells quickly and sheep's cells after 5 min., but not human cells of groups *B* and *O*, or those of some other species.

The fact that the cells of some species are agglutinated by extracts which fail to agglutinate the cells of other species indicates that the former possess certain red-cell receptors which are lacking in the latter. It was therefore considered instructive to determine the reactions of several plant extracts upon the red cells of many species. The antigenic composition of the various bloods in relation to the numerous plant antibodies might thus be established; and if differences are found to exist, a simple means of identification of these bloods might become available. Accordingly, in a preliminary experiment, extracts of *Ricinis communis*, *Dolichos lablab*, *Vicia faba* and *Phaseolus lunatus* were each put up against cell suspensions obtained from the bloods of the following species: sheep, goat, water buffalo, cow, horse, dog, chicken, pigeon, rabbit, guinea pig, and man (groups *A*, *B* and *O*).

The extracts were prepared by the simple mortar-and-pestle method of Boyd and Reguera[3]. 2 per cent suspensions of fresh unwashed cells of the various species were tested against each extract by the tile method, as in simple human blood-grouping, and the results read macroscopically within ten minutes. Negative results were checked under the microscope.

AGGLUTINATION REACTIONS OF VARIOUS ERYTHROCYTES WITH CERTAIN PLANT AGGLUTININS

	Ricinis communis	*Dolichos lablab*	*Vicia faba*	*Phaseolus lunatus*
Sheep	+	—	—	—
Goat	+	—	—	—
Buffalo	+	—	—	—
Cow	+	—	—	—
Horse	+	—	—	—
Dog	+	—	—	—
Chicken	+	+	—	—
Pigeon	+	+	—	—
Rabbit	+	+	+	—
Guinea pig	+	+	+	—
Man (group *B*)	+	+	+	—
Man (group *O*)	+	+	+	—
Man (group *A*)	+	+	+	+

It quickly became evident that there are differences in the erythrocyte antigen pattern of various species (see table). So far the following different groups can be recognized, the members of which are apparently indistinguishable from one another :

Sheep—goat—buffalo—cow—horse—dog.
Chicken—pigeon.
Rabbit—guinea pig—man (groups *B* and *O*).
Man (group *A*).

Testing at a higher level, by using a wider range of plant extracts, might enable a more complete differentiation of various bloods to be made. For example, soya bean extracts are said to agglutinate rabbit's red cells[4] but not human red cells[3].

The experiments described do not take into consideration the likelihood that differences, *vis à vis* plant antibodies, might exist among individual members of each of the species tested. This aspect will have to be fully examined before any firm conclusions can be established. The possibility of differences occurring in the activity of varieties or strains of each of the plants used must also be considered. Minor differences may also arise if a more delicate technique is employed.

It is felt, however, that the differences so far noted are sufficiently striking to merit publication at this stage. Further investigation might be of zoological, botanical, and possibly forensic interest.

A Precursor of Methoxy-*para*-benzoquinone in Wheat Germ

IN September 1952 a preliminary communication was read at the Second International Congress for Fermentation Industries held at Ostend, in which we demonstrated the formation of methoxy-*para*-benzoquinone from an aqueous germ extract. The method used differs from that of Vuataz[1] and of Cosgrove *et al.*[2] in that we did not use any yeast but treated our germ extract with potassium iodate in acid medium. From this we concluded that the germ extract contains the precursor of methoxy-*para*-benzoquinone, and we mentioned the isolation of this precursor (*X*).

Isolation was accomplished in the following way. An aqueous extract of fat-free germ was boiled and treated with 75 per cent alcohol to remove part of the proteins. The rest was concentrated *in vacuo* and extracted with acetone. This was in turn distilled off *in vacuo* and the rest dissolved several times in absolute alcohol, treated with increasing concentrations of benzene up to three times its volume and passed through a column of aluminium oxide. Elution with 85 per cent acetone gave a concentrated solution of *X*. Purification resulted in a white crystalline powder melting at 202°. A very sensitive reaction for *X* is the formation of methoxy-*para*-benzoquinone mentioned above, that is, the addition of iodate in acid medium and demonstration of the benzoquinone with aniline (red colour). By chromatographic methods the hydrolysate of *X* was shown to contain glucose and methoxyhydroquinone (MHQ). From this fact and a number of other reactions, we concluded that the *X* substance was in all probability a monoglucoside of methoxyhydroquinone.

We have now succeeded in synthesizing this product in the following way :

$$\text{Vanillin} \xrightarrow{H_2O_2} \text{MHQ} \xrightarrow{\text{Penta acetylglucose}} \text{tetra-acetate of the glucoside of MHQ} \xrightarrow{Ba(OH)_2} \text{glucoside of MHQ.}$$

This substance, melting at 202° C., did not give any depression of melting point when mixed with the natural product obtained from germ. Moreover, it gave the same reaction with : (1) iodate in *p*H 3·7 buffer with aniline; (2) the Ehrlich diazo-reagents; and (3) the 2,6 dichloroquinone-chlor-imide. The light extinction curves were identical and gave maxima for (1) at 5150 and for (3) at 6000 A. As toluene sulphonic acid was used as a condensation catalyst in the reaction with penta-acetyl-glucose, the formation of a β-glucoside structure is highly probable. The only thing not definitely settled in the structure of *X* is the place of the glucoside binding. This can be either *ortho* or *meta* to the OCH_3-radical. In an analogous way, the glucoside of the dimethoxy hydroquinone (*XX*) was synthesized.

Neither *X* nor *XX* show any improving action on wheat dough. This is in contrast with our earlier investigations on the improving action of quinones[3,4].

In analogy to the work of Neuberg[5] on the glucosidase activity of yeast on arbutine (a glucoside of hydroquinone) we found that even in synthetic nutrient medium the glucoside linkage of *X* was ruptured by yeast. By chromatographic methods the presence of methoxyhydroquinone and glucose could be demonstrated. There are a few conditions necessary to demonstrate the formation of methoxyhydroquinone, namely, absence of sugar in the medium as well as the absence of air and peroxidative enzymes. In the presence of oxygen and still more quickly in the presence of a peroxidative enzyme and oxygen, methoxyhydroquinone will be oxidized to methoxy-*para*-benzoquinone, as can easily be demonstrated by the aniline reaction without iodate.

An emulsion of almonds can also split *X*, and in all probability all leaves containing analogous glucoside compounds have a glucosidase capable of splitting *X*. The presence of a glucosidase in the germ fraction from the mill can also be proved. This must be ascribed to parts of the endosperm.

The slight red tinge of a germ dough after standing longer, or better still after longer contact with yeast, is an indication of the formation of methoxy-*para*-benzoquinone. The presence of the glucosidase action in germ (the formation of methoxyhydroquinone from *X*) can be demonstrated in aqueous enzyme extracts by working in oxygen-free media or in media of a slightly reducing nature. By the decrease in *X* with time as well as by spot reactions on filter paper with the Ehrlich diazo reagent in ammonia vapour or by the reduction of 2,6 dichlorphenol indophenol, the formation of methoxyhydroquinone from *X* can be followed. In the presence of air the methoxyhydroquinone (MHQ) is oxidized to methoxy-*para*-benzoquinone (MPQ), which in its turn is partially coupled with an unknown substance to produce a red-brown colour.

Consequently, the following reaction of *X* is as shown:

$$X \xrightarrow{\text{glucosidase}} \text{MHQ} \xrightarrow[\text{with or without peroxidase}]{\text{oxidation}} \text{MPQ}$$

$$\text{MPQ} \begin{cases} \nearrow \text{(1) irreversible binding of SH-amino-acids.} \\ \rightarrow \text{(2) reversible oxidation of SH to S—S.} \\ \searrow \text{(3) deamination to aldehydes.} \end{cases}$$

Reaction (1) is only possible if hydrogen atoms are available at two adjacent carbon atoms of the benzene nucleus. Moreover, the demonstration of such an enzyme system is of importance for dealing with the problem of the physiological function of *X*. The general opinion is that such glucosides are formed for storing poisonous substances (in this case methoxyhydroquinone) in physiologically inactive form, formed as a by-product of one of the processes of plant metabolism. An alternative is that this *X* substance—while in itself physiologically inactive—can act (after enzymatic decomposition) as a physiological agent or regulator of some process occurring during certain stages in plant-life. Both methoxyhydroquinone and its oxidation product methoxy-*para*-benzoquinone are substances with marked physiological activity. It will probably depend on the stage of plant-life which of these two possibilities, that is, formation or hydrolysis of *X*, will occur.

Thyroid Hypofunction and the Development of the Central Nervous System

METHYL thiouracil depresses the thyroid, and the brains of rats made cretinous with this drug grow proportionately less in length than they do in width or height[1]. Further results of this treatment are that myelination is retarded[2] and that the pyramidal cells of the lamina ganglionaris of the sensori-motor cortex are smaller and more closely packed than in normal animals[1]. The spaces between the cell bodies are occupied for the most part by neuroglia, blood vessels, axons and dendrites, and an attempt to find an explanation for the closer aggregation of the cell bodies in cretins has been made by analysing the rate of growth of each of these components.

It has been found that the volume of glial tissue in the cretinous rats was increased rather than decreased in relation to the normal, so that a change in the amount of supporting tissues does not account for the reduced intercellular spacing characteristic of the cerebral cortex of the cretin. It has also been found that the volume of cortical tissue occupied by blood vessels was slightly, though not significantly, increased in the brain of the cretins. Decreased vascularity cannot, therefore, be the explanation of the closer packing of the neurones. There was, however, a significant difference between cretins and normal animals in the size and distribution of the vessels. In general, the number of vessels 5 μ in diameter or smaller (capillaries) was less in the tissues of the cretinous than of the normal rats, while the number of large vessels (exceeding 5 μ in diameter) was significantly greater. The difference was most marked in those cortical lamina (3, 4 and 5) which are normally the most vascular. Furthermore, there was a general increase in the mean size of the blood vessels in the tissues from the cretins, notably of the capillaries in all laminæ, and of the large vessels in those laminæ nearest the cortical surface.

Other significant differences emerged from a study of the axons and dendrites. The number of axons present in silver-impregnated sections proved to be significantly fewer in the sensori-motor cortex of the cretinous than of the normal rats. Furthermore, although the mean number of dendrites arising from the pyramidal cells in layer 5 (Golgi–Cox preparations) was slightly greater in the cretins than in normal animals, these processes branched less frequently and were significantly shorter. The dendritic fields associated with the pyramidal cells were thus less dense in the brain of the cretin than in the normal. It seems, therefore, that the closer packing of pyramidal cell bodies in the tissues of cretinous rats can be attributed to a deficiency in the growth of neuropil as well as to a retardation in myelination.

The development of the neuropil is generally thought to be a highly significant index of the functional maturation of the cerebral cortex[3,4], and a disturbance in this respect, superimposed upon the disorders of metabolism normally associated with hypothyroidism, may therefore be regarded as contributing largely to the abnormalities of behaviour associated with cretinism.

There is at present little evidence to show whether the changes reported here are the direct effects of thyroid deficiency on nervous tissues or whether they are secondary disturbances. In this connexion, the fact that the brain of the cretin is distorted in shape is probably significant. This abnormality differs only in degree from that which follows hypophysectomy during infancy[5], a condition which has been attributed to a disproportionate growth of the brain and endocranium resulting from a failure of endochondral growth at the basi-sphenoid/pre-sphenoid and spheno-occipital synchondroses. Such incompatability in growth relationships would tend to increase intracranial pressure, which, by restricting the venous drainage from the brain, might be expected to lead to an engorgement of the capillary bed and post-capillary drainage channels in a manner consistent with the experimental observations reported above. Conditions of this kind would inevitably lead to stagnant anoxia, which is known to cause severe damage to developing nervous tissues[6].

Medication of cretinous rats with thyroxin results in a rapid restoration of somatic growth, and so presumably of normal cranio-neural relationships. Preliminary studies have shown that the recovery is associated with at least a partial restoration of normal behaviour, for animals in which the appearance of automatic reflex responses had been grossly retarded during infancy have, after subsequent treatment with thyroxin, learned to run an elevated T-maze at least as well as normal, and better than untreated, littermates[7]. This finding is unexpected in the light of the widely accepted view that the cerebral changes associated with thyroid deficiency in man are irreversible if therapy is unduly delayed[8]. A possible explanation of this discrepancy is that the maze used was inadequate as a test of higher cortical function, for medicated cretins have so far failed to perform delayed response tests within the capacity of normal rats. On the other hand, the irreversible cerebral changes in many human cretins may be due not so much to thyroid deficiency as to the coincidence of some other congenital defect[9]. A more detailed experimental study of the effect of replacement therapy in the cretinous rat should reveal the relative importance of genetic and endocrine influence on cerebral maturation.

Formation of Neurofibrils in the Brain of a Human Foetus 28 Weeks Old

FROZEN sections of formalin-fixed tissue of a human foetus 28 weeks old were impregnated with silver, using Bielschowsky's technique to show neurofibrils, and stained by other methods. Detailed histological findings will be published later.

Very fine and coarser fibrils were numerous in the deepest one-third of the cerebral cortex bordering the central fissure; elsewhere in the cerebral cortex there were a few coarse fibrils. Fine and coarser fibrils were present also in the cerebral white matter and in subcortical centres. Where the production of fine fibrils had occurred in the cortex, nuclei were relatively large, widely spaced and possessed a more mature nucleolar structure than was seen elsewhere in the cortex (Fig. 1). Except in occasional instances deep in the postcentral cortex, perinuclear cytoplasm was not seen either in silver preparations or after staining with azur *A* at *p*H 4. The globus pallidus also contained numerous fine fibrils, lying outside nerve cells in the cytoplasm of which neither Nissl substance nor neurofibrils were demonstrable (Fig. 2). The latter structures, although not Nissl substance, were seen in the same preparation within occasional nerve cells in the external reticular nucleus of the thalamus. There was no demonstrable continuity between intra- and extracytoplasmic fibrils.

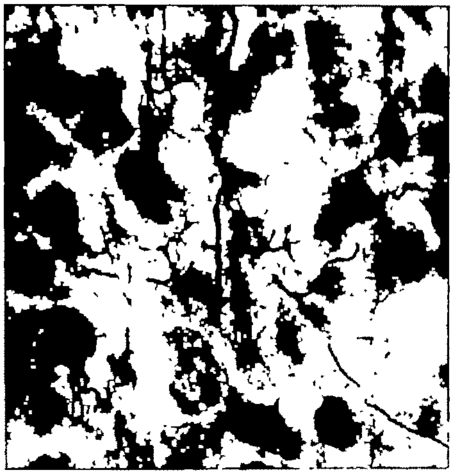

Fig. 1. Cerebral cortex treated by Bielschowsky neurofibril method. (× 1,000)

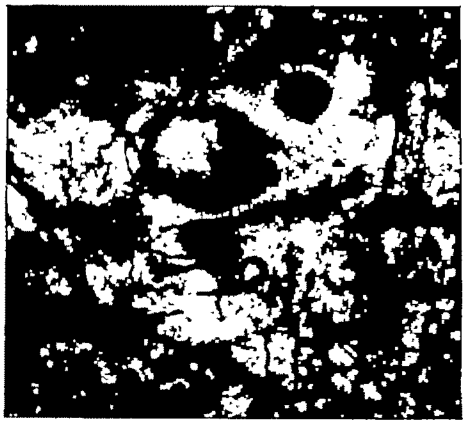

Fig. 2. Globus pallidus, same method. (× 1000)

Extracytoplasmic fibrils were thus already present in large numbers. Centres from which afferent fibres might have originated (to cortex, lateral part of thalamus; to globus pallidus, putamen and thalamus) were, on the other hand, markedly immature. For these reasons the possibility of more than a very few of the observed extracytoplasmic fibrils being axonal terminals could not be entertained.

The histological differentiation of neurones is thought to correspond to the onset of nucleoprotein synthesis by the maturing cells[1]. Fibrillogenesis in the central nervous system may therefore be the precipitation of a fibrous protein within an intercellular substance such as exists in membranous connective tissue[2], elaborated in this instance by developing nerve cells. Ultra-microscopic appearances suggest the presence of a similar ground substance in the adult mouse cerebral cortex[3].

The fibres which have been described probably serve as a framework for subsequent neuronal development in the growing brain. Chemical changes attending their production are not known. A study of the metabolic aspects of their origin might form a link between observed histological phenomena and protein synthesis.

Neurohæmal Organs in Crustaceans

A NUMBER of structures of nervous origin in the higher Crustacea have recently been described under a variety of names, although they show a unity of structure and possibly of function. We wish to propose, tentatively, a common name to denote organs of this type in crustaceans, in order to avoid a needless multiplicity of names for organs which have many features in common. The organs are: the sinus gland of the eyestalk[1,2]; part of the pars distalis of the *X*-organ of the eyestalk[3,4]; the sinus plate or post-commissural organ of the tritocerebral region[5]; the pericardial organs of decapods[6]; the dorsal lamellæ of the pericardium of *Squilla* and the associated system of dorsal trunks[7]; the transverse bar in the ventral blood sinus of the sixth thoracic segment of *Squilla* and the associated system of median connectives[8]; the apparatus nervi dorsalis cordis of the crayfish[9]; the neuropiles, or punctate substance, which extend over the ligaments of the heart in *Palinurus* and *Scyllarus*[10].

Each of these structures consists of the endings of nerve fibres, located in or alongside the walls of blood vessels or blood cavities, or even in the blood itself. The authorities cited in the list above are not always those who first described the organ concerned but who showed that it had this nature. The nerves running to these organs, are, apparently always, efferent, but do not supply any muscle; the organ to which they run is formed mainly from their own endings. The first five listed have been shown to contain hormonal material[1,2,3,11]; the function of the others is unknown; it may be that they, too, are endocrine organs.

It seems preferable to call these organs by some purely topographical name which does not denote any function, actual or supposed. The adjective 'neurohæmal' seems to us to be the most appropriate topographical name denoting the common feature of these organs. The organs may thus be referred to collectively as neurohæmal organs, while the adjective may be combined with any of the pre-existing names for these various organs, as, for example, 'the post-commissural neurohæmal organ' and 'dorsal neurohæmal lamella'.

The neurohæmal organs of the higher Crustacea are of two chief kinds. The first type Alexandrowicz has referred to as 'neuropiles', in which the organ is made up of fine, ramifying nerve-endings, between or along which are found numerous small droplets. The post-commissural neurohæmal organ, the transverse neurohæmal bar, the dorsal neurohæmal lamellæ, the pericardial neurohæmal organs and the neurohæmal organs of the heart ligaments are all neurohæmal neuropiles. Certain authorities in conversation have objected to the use of the term 'neuropile' in this context on the grounds that it was coined to describe areas in the central nervous system. It is true that the term was first used in this way; but standard definitions of the word, such as that of Hanström[12], give it a purely descriptive significance with no topographical connotations. We may distinguish between the well-known central neuropiles and these less-known peripheral neurohæmal neuropiles which, however, still come within the definition of the term 'neuropile'. The second type of neurohæmal organ is believed to be made up of enlarged nerve-endings. The sinus gland, the neurohæmal portion of the *X*-organ and the apparatus nervi dorsalis are neurohæmal organs of this second type.

We feel that the term neurosecretory organ or system should be reserved for the entire complex, comprising nerve cell bodies, nerve fibres and neurohæmal organ, which produces, transports and releases the neurosecretion; it should not be confined to or used for a neurohæmal organ by itself. Under this terminology, the complex pars ganglionaris *X* organi, sinus gland tract and sinus gland form a neurosecretory system, and sinus gland itself is a neurohæmal organ.

A neurohæmal organ is therefore defined as a crustacean organ composed of a group of nerve-endings bearing close spatial relationship to the blood-vascular system.

This proposed nomenclature has been discussed at the recent symposium on neurosecretion held at the Zoological Station, Naples, during May this year, and received general support.

A New Method for determining the Transition Temperature of Insect Cuticular Waxes

BEAMENT[1–3] has described three methods for determining the transition temperature of insect cuticular waxes. For studying the influence of culture temperature on the transition point of the waterproofing wax in insect eggs, however, none of these methods is suitable, since either (*a*) the determinations are made on batches of several eggs, so that individual variation is obscured, or (*b*) the end-point is not sharply defined.

Preliminary experiments have now been carried out, using an electrical method which it is believed is capable of giving results accurate to ± 0·1° C. The material used was three-day old eggs of *Rhodnius prolixus*, which have a waterproofing wax layer inside the chorion; but the method is readily adaptable to other types of material.

A fine capillary filled with $M/10$ potassium chloride solution is sealed into the egg. A non-polarizing electrode leads from this capillary, and another non-polarizing electrode from the vessel of $M/10$ potassium chloride solution in which the egg is immersed. The vessel is heated slowly by suspending it in a water-bath, while an externally applied potential difference is maintained between the two electrodes; the current flowing across the egg membranes is noted as the temperature rises.

Over a range of 2 deg. C. on either side of the transition temperature, the curve of current/temperature obtained is similar to the permeability/temperature curves obtained by Beament[4], suggesting that in this connexion current (which is proportional to ionic permeability) may be used as an indication of the water permeability at a given temperature. The transition temperature may be defined as the point on the curve where d^2i/dT^2 is maximal, at which point it is considered that the greater part of the components of the wax layer passes through the transition.

Values of the mean transition temperature for a number of eggs from each of three cultures agree broadly with those obtained by Beament.

Material. Eggs from :	Mean transition temperature (° C.)
(a) ♀♀ kept for 3 weeks at 23° C.	41·64 ± 0·13
(b) ♀♀ cultured at 28° C.	42·28 ± 0·20
(c) ♀♀ kept for 8 days at 32·5° C.	42·43 ± 0·12

The differences between the mean transition temperatures are statistically significant at 0·01 per cent.

Radioautographic Study of the Localization of Tobacco Mosaic Virus Antigen

THE localization in animal tissues of injected antigens has been, during recent years, the object of a great number of investigations in order to identify the cells responsible for antibody production. This problem is related to the more general one of the localization and mechanism of protein synthesis.

An important contribution to these studies has come from the use of chemically[1,2] and isotopically labelled antigens. Antigenic iodoproteins labelled with iodine-131 have been used in most cases[3] and their localization in liver mitochondria has been established by Haurowitz and Crampton[4,5]. Libby and Madison[6] have, on the other hand, used as antigens tobacco mosaic virus labelled with phosphorus-32 and found that they were localized chiefly in the liver, but also in the spleen; this reaction is related to the production of antibodies. However, these investigations have not definitely clarified the nature of the specific cell-types responsible for antibody production: some authors[7] emphasize the role of the reticulo-endothelial tissue (young reticular elements, histiocytes, plasma cells, macrophages); but others believe in the major contribution of lymphoid cells[8,9].

The method used for our investigations was as follows. Radioactive tobacco mosaic virus was crystallized from infected leaves grown in an atmosphere of carbon-14 dioxide; a concentrated solution (± 10 mgm. containing 32·000 c/m.) was injected intravenously into mice. Blood was collected at different intervals and, in the case reported here, the mouse was killed on the fourth day after the injection. The tissues were fixed in acetic alcohol, embedded and sectioned at 6 μ. Blood and bone marrow smears were fixed with methanol. Both the histological slices and the smears were covered with photographic emulsion 'in gel form' (G_5 Ilford) 40 μ thick, when dried.

This method makes it possible to localize individual beta-ray tracks coming from the carbon-14. After 2–6 days exposure, the slides were developed in amidol-sulphite at *p*H 7–8 and fixed in 30 per cent saturated hyposulphite. Histological sections were stained with methyl green – pyronin, and the smears with Giemsa solution. It was found that a preliminary treatment in 75 per cent ethanol increases considerably the diffusion of the dyes through the emulsion.

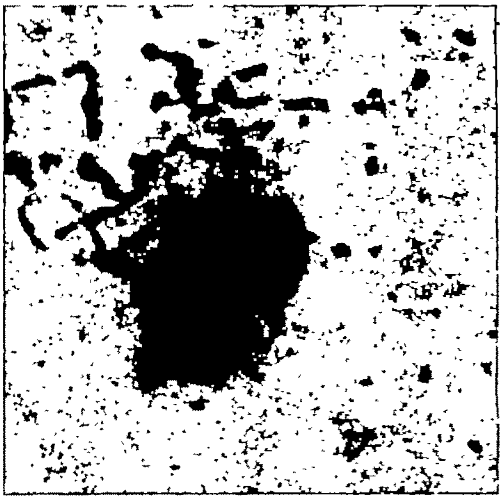

Fig. 1. Plasmoblast in the bone marrow with numerous tracks emitted by the cytoplasm only

The following experimental results were obtained.

Blood. Beta-ray tracks were counted in smears prepared at different times after injection; radioactivity of the cells fell to 50 per cent of the initial value after 3 hours, and afterwards this drop was much slower. After 48 hours, one-third of the initial activity was still found. This pattern was confirmed by direct counts in a Geiger–Müller counter. No tracks were observed in either red or white blood cells; apparently virus remains in solution without being incorporated in the corpuscles.

Bone marrow. Cells of the granulocytic or erythrocytic lines do not contain any activity. On the contrary, the reticular cells (young reticular elements, histiocytes, plasma cells) are highly radioactive. The beta-ray tracks are of cytoplasmic origin (Figs. 1 and 2). Observation of the other tissues demonstrated that spleen had the highest activity; liver was also very active. Conversely, incorporation was much less in the lymph nodes, kidney and lungs, and scarcely detectable in muscle.

Spleen. Cells of the red pulp and of the venous endothelium fixed a considerable amount of antigen.

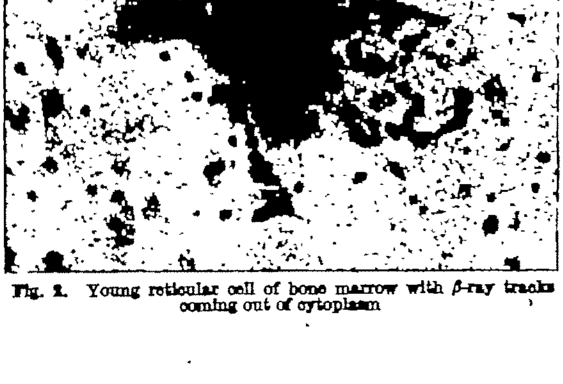

Fig. 2. Young reticular cell of bone marrow with β-ray tracks coming out of cytoplasm

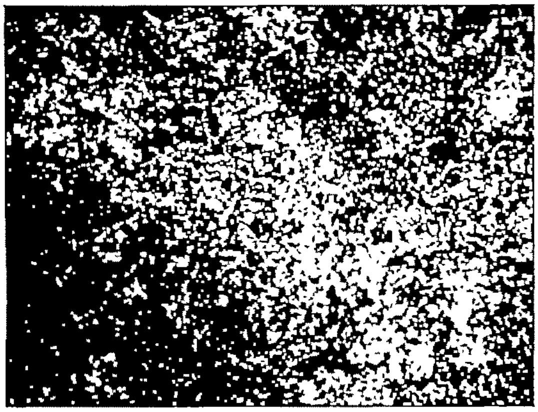

Fig. 3. Region of the spleen: (a) red pulp; (b) quadrant of a lymphocyte follicle (white pulp); (c) central area of the follicle

Young reticular elements having a highly basophilic cytoplasm were found to be the most active. The radioactivity of the lymphoid follicles was only slightly above that of the background. However, in the centre of the follicle, where younger and larger cells were found, there was a measurable incorporation (Fig. 3).

Liver. Numerous beta-ray tracks were found in the Kupffer cells, and also in the hepatic cells, most of which were proximate to the portal spaces. Here also, most tracks originated from the cytoplasm; however, some rare nuclei appeared to emit electrons.

Lymph nodes. Radioactivity was considerably less than in the spleen and liver and chiefly localized in the endothelial cells of the sinuses.

Kidney. Although the kidney was found to be slightly radioactive, it has not been possible to determine if this activity crossed the glomerular barrier.

Lung. This was also found to contain weak activity, mainly localized in the connective and vascular tissue.

In conclusion, these observations allow us to conclude that the tobacco mosaic virus injected intravenously as an antigen is chiefly concentrated, after four days, in the spleen which is enlarged. The young and highly basophilic elements of reticular origin, which are considerably increased in number, seem to play a predominant part in the early steps of the antigenic reaction.

We are greatly indebted to Prof. R. Jeener for the preparation of labelled tobacco mosaic virus.

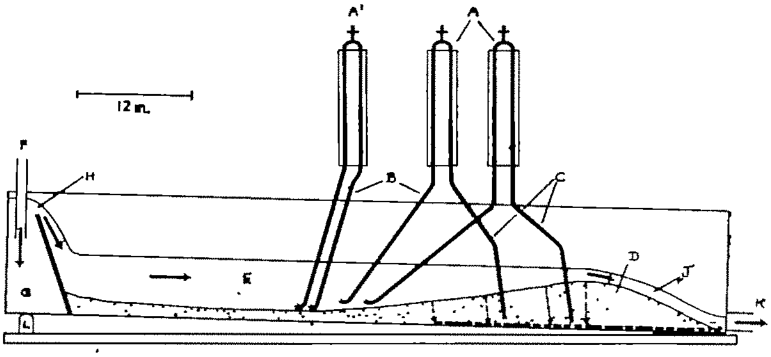
Water Currents through Permeable Gravels and their Significance to Spawning Salmonids, etc.

Field observations using soluble dyestuffs introduced in crystalline form have demonstrated the existence of a well-defined flow of water beneath the river-bed at such sites as are chosen for the redd by spawning salmon and trout. Situations where the gravel is consolidated beneath the surface are avoided. These observations have considerable interest both as regards 'selection' of spawning sites calculated to afford adequate aeration for ova and alevins and, in a wider context, in the ecology of various invertebrates or their larvæ[1].

It has been found possible to demonstrate the relative values of these currents in a model pool by means of a series of manometers arranged in a specially designed tank (see accompanying diagram).

Manometers, based on the well-known Pitot apparatus for measuring current velocities, are set up so that one limb of each manometer penetrates the gravel bank. The height of the contained water column thus depends on the downward-flowing current in the gravel. The other limb of each manometer rests in the relatively static water in the middle of the pool. A control manometer (*A'*) with two 'static' limbs is also set in position. An indication of the relative strength of the currents at various points in the pool is obtained by comparison of the heights of the water columns in each manometer. The readings obtained from these manometers show that the currents through the gravel are remarkably consistent and the water columns are not subject to the rapid fluctuations associated with the Pitot tube used in the normal fashion. The apparatus has been found to be equally effective in a natural pool, and its use in the field seems likely to provide an accurate assessment of natural spawning facilities.



Diagrammatic section through model pool.

A, Manometers showing height of water columns; *A'*, control manometer; *B*, static limbs; *C*, limbs inserted in gravel; *D*, gravel bank; *E*, pool; *F*, inflow from mains; *G*, surge chamber; *H*, overflow to pool; *J*, overspill; *K*, outflow from tank; *L*, movable block for adjusting gradient. The broken lines in the gravel bank indicate the paths of the current

It can be shown that these currents are dependent chiefly on the gradient from one pool to the next and not on the velocity of the stream. The manometer readings indicate clearly that the strongest current through the permeable gravel occurs below the apex of the gravel mound and that the currents decrease in strength towards the middle of the pool, where they cease.

The model has demonstrated further that these currents are more positive than had been hitherto realized and also, by the use of dyes and other materials, that their direction downwards through the gravel is approximately at right angles to its surface, irrespective of the gradient of the gravel bank.

The influence of these currents on the distribution of the bottom fauna and flora is being investigated, but it is evident that incubating ova and developing larvæ of salmon, trout and minnows are thus provided with the maximum aeration possible.

Further indication of the biological significance of these currents has been obtained incidentally by the successful spawning of minnows (*Phoxinus phoxinus*, L.) in the experimental tank, no previous record of which is known to me. The ova deposited at the surface of the gravel became lodged in the gravel bank, presumably by the action of the downward currents, and some thousand fry have since been reared in this tank. A full account of this work will be published elsewhere.

Frequency of Moulting in Anura

THERE appears to be no accurate information available on the frequency with which the Anura moult. In his recent monograph on the British Amphibia, Smith[1], discussing the habits of *Bufo bufo* (L.), writes: "Periodically the skin is shed, certainly several times in the course of a summer. Gadow states that they shed it every few weeks, but this surely is an overstatement".

We have investigated the frequency of moulting in two species of *Bufo* and one species of *Breviceps*. The method employed was simple. The animals were kept in isolation in boxes with a dish of water. A small area of the back was painted with Gestetner correcting fluid. This mark comes away with the cast at the time of moulting, which can thus be accurately determined. There is no evidence that the fluid has any adverse effect upon the animals. Observations were made every twelve hours and the animals were maintained at a constant temperature of 20° C. The results obtained are summarized in the accompanying table.

	Bufo regularis Reuss	*Bufo carens* Smith	*Breviceps mossambicus* Peters
Mean duration of intermoult (days)	5·8 ± 0·1	4·3 ± 0·1	5·7 ± 0·2
Maximum and minimum values (days)	3·5–9·5	3·0–6·5	4·0–6·5
No. of animals	80	16	4
No. of observations on each animal	6	5	5

It will be seen that the moulting of these three species is a much more frequent event than had hitherto been suspected. Preliminary observations on *Rana oxyrhyncha* Smith, *Rana umbraculata* Bush and *Xenopus laevis* Dandin indicate that these largely aquatic species moult about once a week; but no satisfactory method of marking has yet been developed which allows accurate quantitative statements to be made.

A fuller account of these results, together with observations on the influence of environmental and other factors on moulting, will be published elsewhere.

Use of X-Ray Stereoscopy for examining Shipworm Infestation *in vivo*

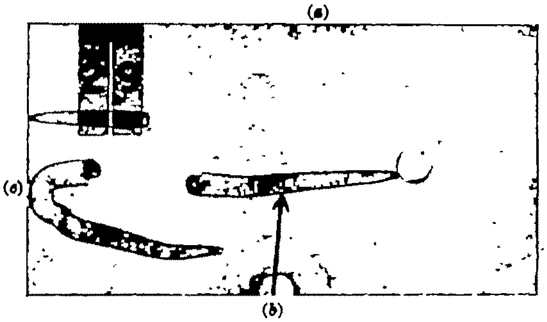
THE ravages of the shipworm, *Teredo* sp., particularly in warmer seas, are notorious. In order to combat these attacks several methods of control are in use. The pretreatment of timber by creosote, preferably under pressure, is normally recommended, though other compounds have also been employed.

Prerequisites to the development of improved treatments are: (*a*) a knowledge of the habits of the larval *Teredo*, its method of entry and selection of points of attack; (*b*) the growth and behaviour of the adult; (*c*) a reliable method of assessing attack by *Teredo* on experimentally treated wood blocks.

Since the *Teredo* enter the wood as minute larvæ, and remain inside, they are scarcely noticed until the block falls to pieces as a result of their activity. Assessment or examination of the extent of attack before this occurs normally involves opening up the wood, as, for example, by planing off the surface[1]. This inevitably terminates the experiment.

Although as early as 1924 a photograph of heavily infested wood taken by means of X-rays was published by the National Research Council, Washington[2], the idea does not appear to have been put to practical use. It is therefore hoped that the details given below will be of assistance to workers investigating measures of control.

In the course of work carried out during the past three years on the efficacy of various methods of treatment of experimental wood blocks we have used X-rays for *in vivo* examination of *Teredo* without causing them or the blocks any injury. This has allowed us to follow the growth and boring habits of individual shipworms from the time of their initial settlement in the wood.



Radiograph of one half of a pine block showing (*a*) newly settled *Teredo* larva, (*b*) typical individual about one month old growing along the grain, and (*c*) burrow turning at the block edge. Two-thirds natural size

The method depends upon the opacity to X-rays of the two reduced valves or head plates at the anterior end of the animal, the posterior accessory pallets, and the calcareous lining which it secretes around its burrow in the wood. Since even the minute valves of the newly settled larvæ show up clearly (Fig. *a*) the actual onset of the attack is revealed immediately. Later radiographs show the extent of the infestation, the position of each animal and its tube being sharply defined against a background formed by the grain of the wood.

A low-power mobile X-ray set was chosen for this work as the tube had low inherent filtration and a 1-mm. focus, ample contrast and resolution being obtained on Ilfex film at 40 kVp., with an exposure of 10 mA./sec. at 30 in. focus-film distance. Using the same film, the work is possible with the smallest portable set obtainable. Infected blocks were scraped clean of surface growths and photographed in the laboratory, lead numerals serving to identify the blocks and to indicate a reference plane. The blocks were replaced in the sea within a few hours of removal for examination. In this way it has been possible not only to follow the whole course of attack in series of experiments on infected blocks, but also to obtain information on the times and preferred positions of settlement, on growth-rates, and growth habits.

With wooden blocks ½–1 in. in thickness it was found desirable to introduce stereoscopy in order to interpret the arrangement of the burrows. A degree of hyperstereoscopy was achieved by moving the stereofilm changer along a track parallel to one side of the film through a distance equal to one-sixth of the focus-film distance instead of the normal one-tenth. This gave an apparent 50 per cent increase in depth in a Wheatstone stereoscope; with greater hyperstereoscopy there was a risk that the conglomerate images of heavily infected wood might be difficult to dissociate. In some instances fiduciary wires were placed along the two sides of the picture space to indicate a surface plane and to measure shadow shifts if required.

Stereographs of heavy infestations taken by this means give a remarkable effect, the tubes being seen in three dimensions intertwined among each other, yet every tube quite isolated from its neighbours.

A paper giving further details of the use of this technique is in course of preparation and will be published shortly.

Occurrence of *Phoronis mülleri* in the Irish Sea

The recent discovery of *Phoronis mülleri* de Selys Longchamps off the west coast of the Isle of Man appears to constitute the first British record of the adult of this species; according to de Selys Longchamps, the larva of *Phoronis mülleri* is *Actinotrocha branchiata* J. Muller, which he states has been found at Millport, St. Andrews, Plymouth and Valencia[1].

There have been no previous records of adults of any species of *Phoronis* in Manx waters; but larvæ, recorded as "*Actinotrocha* sp.", were found in Port Erin Bay from June to August 1899[2]. The discovery of the adult *Phoronis mülleri* was made during quantitative investigations of the offshore polychæte fauna in November 1952. It was found to be common in muddy sand at depths of 37–62 m., and to occur occasionally down to 74 m. in an area between four and seven miles west of the Niarbyl.

Phoronis mülleri was first described from Heligoland, where it was found in muddy sand at 35–37 m.[1]. It was next recorded from the west coast of Sweden, again from muddy sand, at all depths from 9½ to 53 m.[3]. The latest record of which I am aware is from Danish waters, where some post larvæ were found west of the Island of Ven in the Øresund, at a depth of 16 m.[4].

Unlike the two other British species (*Phoronis hippocrepia* Wright and *Phoronis ovalis* Wright), *Phoronis mülleri* is not colonial and does not bore into dead shells. It builds a tube of sand up to 80 mm. long by 1 mm. wide which stands vertically in the substratum. The species may be distinguished from all others of the genus by the shortness of the tentacles on the oral side of the lophophore[1,3].

It appears that *Phoronis mülleri* is restricted to offshore grounds of muddy sand, and it is probable that it will be found to be more widely distributed than it is known to be at present.

Fluorine Tests in Australia on the Keilor Skull and a Tertiary Marsupial

The Keilor Skull. The application of the fluorine-phosphate method described by Oakley and Hoskins[1] for determining the relative ages of fossils has shown that the Keilor Skull from near Melbourne is a true fossil, and its age that of the terrace in which it was found. The ratio $\frac{\%F \times 100}{\%P_2O_5}$ for the skull is 2·0, and of other fossils found *in situ* in the terrace 1·9, 1·5 and 2·9. Different parts of a rat skeleton gave 3·8 and 4·4—higher than anticipated, and due to low percentage of phosphate. I am indebted to Mr. W. R. Jewell, chief chemist, State Laboratories, Melbourne, and his staff for carrying out the analyses.

The various terraces at Keilor can now be recognized by their lithology, their spatial relationships and their soils. There are remnants higher than those reported earlier[2]. The Keilor Terrace is not as old as originally estimated, for a prominent diastem in the Keilor Terrace runs also at the same height through the Braybrook Terrace. The two terraces have the same lithology and the same soil, so the Braybrook Terrace is but a partly eroded Keilor Terrace.

In addition to the evidence of the fluorine test, it is concluded that the Keilor Skull could not be a burial because even on present levels it would mean an excavation of 9 ft. from the surface of the terrace or 25 ft. from the bank of Dry Creek. Also one would expect to find much more than the skull if a comparatively recent intrusive burial had occurred. Deposition of the Keilor flood-plain has nothing to do with eustatic sea-levels, in my view, but was a function of restriction by the narrow winding gorge at the downstream end of the flood-plain in a time of higher rainfall. Since then, the river has cut down to bedrock, deposited the Maribyrnong Terrace, and the sediments of the Keilor Terrace (including the Braybrook Terrace) have been oxidized. In the lower part of the Maribyrnong River (from the banks of which the Keilor Skull came), deposits associated with eustatic changes of sea-level have been traced for more than eleven miles along the river, and the relationship of these to the terraces is under investigation.

An official police inquiry has shown that there was not a second skull as earlier reported[3]. The misunderstanding arose apparently from lack of knowledge of bones by the sand contractor who signed the statement. War-time conditions precluded full investigation at the time. Even if the Keilor Skull had proved to be a burial, the charcoal, calcined bones, red ochre and implement found together in the terrace (apparently associated with the diastem) provide sufficient evidence of human occupation at the time the Keilor Terrace was being deposited. The skull was a few feet from the lenticle of charcoal, etc.

Tertiary Marsupials. A fragmentary ramus of the mandible of a marsupial was found some years ago in a Lower Pliocene marine shell bed near Hamilton, Victoria. The fluorine test, foraminifera and matrix obtained from a tooth cavity and around the base of a tooth, and the circumstances of collection all combine to establish the validity of this important fossil. A well-preserved third molar tooth is hypsodont and sharply bilophodont, showing the typical specialization for the grassland habitat. It is a *Macropus* in the wide sense, and proves that the Macropodidæ did not evolve in the late Tertiary (cf. ref. 4, p. 12).

In a fossil podsol-soil with Tertiary plants in position of growth, overlying the marine beds from which came the *Macropus*, and sealed off by a basalt flow, I have found an upper molar of a cuscus. The soil is almost certainly of Upper Pliocene age[5]. A subtropical rain-forest environment is suggested by both the cuscus and the associated flora.

The known Australian Tertiary marsupials are now therefore three in number, namely:

Period	Fossil	Habitat
Upper Pliocene	Cuscus	Rain-forest
Lower Pliocene	*Macropus* (kangaroo)	Grassland or open forest
Lower Miocene to Upper Eocene (authors vary on age)	*Wynyardia bassiana* (possum)	Forest

The first two come from Victoria and the third from Tasmania. Two are phylangerids and one a macropodid. All are diprotodonts and herbivores. All are of sizes comparable with their extant congeners, and the evidence (so far as it goes) suggests that the marsupials were small in the Tertiary, giant in the Pleistocene, and small again in the Holocene. The small forms co-existed with the giant ones in the Pleistocene, but in much smaller numbers, judging by the number of fossils found. The process of switching back to smaller forms appears to be still going on, for the bigger kangaroos are tending to die out, whereas the small marsupials are thriving. Five sites indicate that the Australian aborigines were here in the time of the giant marsupials, so since then the aborigines have had to adjust themselves to climatic changes, to the attendant vegetational and physiographical changes, and to changes in their food fauna and flora.

Full details of the above and associated investigations are being published in the *Memoirs* of this Museum.

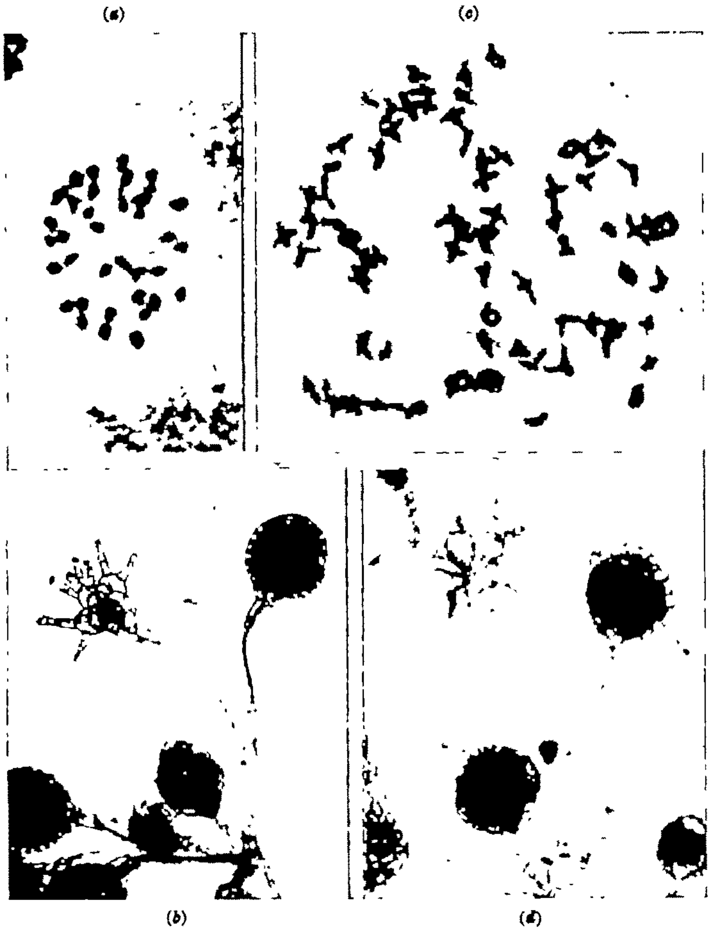
Two Cytological Forms of *Polypodium virginianum* in Eastern North America

P. virginianum L. is the only representative of the *P. vulgare* complex which is known to occur on the eastern seaboard of North America. It has hitherto been regarded as a well-characterized species readily distinguishable from all others by the possession of a striking type of stellate paraphysis which has been intensively studied by Martens[1] and his collaborator, who regard them as modified sporangia. The chromosome number has previously been reported by one of us to be diploid[2].

Fig. *a* shows a metaphase plate obtained in 1953 from the diploid plant from Halifax, Nova Scotia, previously described and figured. The chromosome number, as stated, is 37, and one of the characteristic paraphyses is illustrated in Fig. *b*. We have a similar diploid plant, obtained afterwards from near Ottawa, which was referred to in a later publication[3] as coming from the province of Ontario. This attribution is not quite correct, since we have now learnt that the original site of collection was "on the Gatineau river, 10 miles north of Ottawa", and therefore actually over the border into the province of Quebec. It is, however, also diploid, as stated, and it serves to show that this form of the species is probably the prevailing one, at least in the regions immediately adjacent to the St. Lawrence estuary.

A third plant of the species posted to us in 1948 but only recently examined is, however, not diploid. It is a tetraploid without quadrivalents (Fig. *c*), but it nevertheless bears stellate paraphyses of the same general type as the preceding (Fig. *d*). They are less numerous, being only about four per sorus instead of about twenty per sorus, and the cell size is larger. There may be other morphological differences, but the range of form in paraphyses of the same plant is so varied that precise comparisons are not easy. The plant came from "10 miles north of Kingston, Ontario".



(a) First meiotic metaphase of *P. virginianum* from Nova Scotia with $n = 37$. (× 1,000.) (b) Sporangia and a paraphysis of the same. (× 50.) (c) Diakinesis in the tetraploid to show absence of quadrivalents. (× 1,000). (d) Sporangia and paraphyses of the tetraploid. (× 50)

On the basis of only a single specimen of the tetraploid, we cannot usefully attempt a full morphological comparison of the two forms, though it is to be hoped that with more ample material it will be possible to detect some simple diagnostic differences for distinguishing them in the field. We therefore wish to direct the attention of local American or Canadian botanists to this problem, and we would welcome further information or material which might elucidate the relative geographical distributions of the two forms.

Their genetical affinity is in the meantime being investigated in Leeds.

Factors affecting the Regeneration of Root-Cuttings

ROOT-CUTTINGS can be used for the rapid vegetative propagation of many plants; but, despite certain advantages, the method has not been widely employed in British horticultural practice, possibly because of its apparent uncertainty. Batches of cuttings which appear to be quite suitable may sometimes give a high proportion of successes and at other times fail completely. Recent work on the regeneration of root cuttings may throw an interesting light on this question.

Most of the initial work was done with raspberries (*Rubus idaeus* L.) of the varieties Lloyd George and Malling Promise. Roots were dug at intervals during a period of four years from plants up to two years old and made into cuttings, which were mainly 8–12 cm. long and 2–4 mm. in diameter. The cuttings were inserted horizontally in three different environments: namely, heated glasshouse (58 batches, comprising a total of 1,507 root-cuttings planted 2–3 cm. deep); unheated frames (24 batches, 648 cuttings, 2–3 cm. deep); and open ground in full sun (46 batches, 1,093 cuttings, 3–5 cm. deep).

Although all the roots used were healthy, usually well-furnished with buds and apparently ideal propagating material, the proportion of root-cuttings which regenerated varied widely between different seasons of the year. Most of those taken from May to July died, but from August to April a higher proportion regenerated, and by far the greatest percentage of successes were from cuttings taken in the winter months.

Such a marked seasonal effect was not unexpected. The work of propagators such as Stewart[1] at the Royal Botanic Garden, Edinburgh, has shown that stem cuttings of many species regenerate more readily at one season than another, and it was therefore not surprising to find that roots also showed a rhythmic seasonal response to propagation by cuttings.

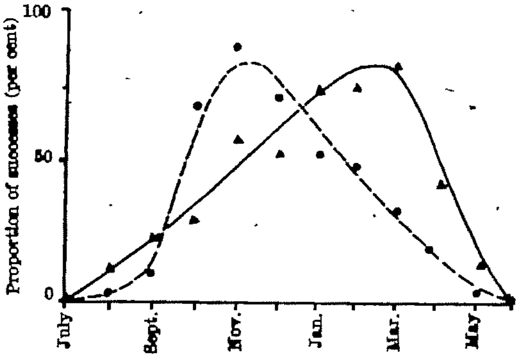
However, further analysis shows not only well-marked 'on' and 'off' seasons for the propagation of raspberry root-cuttings but also distinct trends in their responses to different environments at different seasons. These trends are indicated in the diagram, which shows the results of a typical year's work with the variety Malling Promise. Results in other years and in experiments with the variety Lloyd George have shown similar trends.

During the 'on' season, from autumn to spring, the proportion of successes in the glasshouse tends to rise to a peak for cuttings inserted during the months of January, February and March. On the other hand, out-of-doors the peak is reached much earlier, the best results being given by cuttings taken soon after the beginning of the 'on' season, with a decreasing proportion of successes from cuttings put in thereafter. Cold frames provide a micro-climate intermediate between a heated glasshouse and the open

[1] Martens, P., *Bull. Jard. bot. Brux.*, 17, 1 (1943). Martens, P., and Pirard, N., *La Cellule*, 49, 385 (1943). Pirard, N., *La Cellule*, 51, 155 (1947).

[2] Manton, I., "Problems of Cytology and Evolution in the Pteridophyta" (Cambridge, 1960).

[3] Manton, I., *Nature*, 167, 37 (1951).



Months of the year (July 1951–June 1952)
●—●—, Cuttings inserted out of doors; ▲—▲—, cuttings inserted in heated greenhouse

ground, and cuttings in this environment behaved in an intermediate way.

Thus success or failure in the propagation of raspberry root-cuttings appears to depend primarily on an annual rhythm which may be strongly influenced by environment. Cuttings taken during October or November are most likely to grow if given natural winter temperatures by planting out-of-doors, whereas those taken from December to February respond better if put in a cold frame, and from March to the end of the 'on' season the highest proportion of successes comes from cuttings put in a heated glasshouse. Thus it appears that, the later cuttings are taken in the 'on' period, the warmer must be the environment to promote growth and regeneration.

The experiments have been extended to include the propagation of a wide range of herbaceous and shrubby plants by root-cuttings grown under various environmental conditions, and it is hoped that the work may clarify the position, enabling a higher proportion of successes to be obtained, with certainty, by the use of root-cuttings. It is too early yet to suggest any generalizations, but there are indications of well-marked 'on' and 'off' seasons for the propagation of other species by root-cuttings and that the optimum temperature conditions for propagation may vary from one period to another within the 'on' season, as in the case of raspberries. The best season for propagation may thus depend on the nature of the environment into which the root-cuttings are to be put to grow.

The choice and preparation of raspberry root material, methods of making and planting the root-cuttings, and the subsequent management of the plants produced will be described in detail elsewhere.

Diacetyl as a Flower Scent

A recent publication by Derx[1] recorded diacetyl as the cause of the butter-like scent of the flowers of *Fagraea racemosa* Jack. (Loganiaceae); another case of the same phenomenon can now be recorded. This new observation was also made in the Botanic Garden at Bogor, Java. A flowering specimen of *Polyalthia canangioides* Boerl. var. *angustifolia* (Anonaceae), a beautiful tree, exhaled a heavy odour of fresh butter. Some flowers were tested, with positive results, for the presence of diacetyl by the method described by Derx. The red, dichroitic, crystal needles of dimethylglyoxime–nickel appeared within 30 min., so it was concluded that in this case, too, the smell of the flowers is caused by diacetyl. Diacetyl has thus been found in flowers of plants belonging to different families.

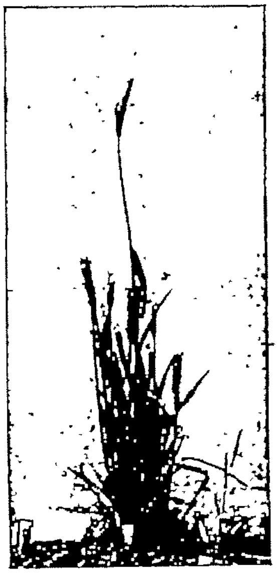
Behaviour of a *Triticum* × *Secale* Hybrid under the Action of Colchicine

In the spring of 1952 an attempt was made to double the chromosome number of a single wheat × rye F_1 hybrid plant with the object of obtaining a fertile amphidiploid. In view of the limited material available a method of injecting the culms with 0·05 per cent colchicine was adopted.

One culm, a little more advanced than the rest, was not treated since it was believed that the stage of meiosis had already been reached. It grew normally and gave a sterile spike typical of F_1 *Triticales*. The treated culms were injected 5–7 times, but this was found to be excessive. Growth stopped, the last node and subjacent region showed c-tumors, and the upper tissues were destroyed and no spikes developed. Adjacent, untreated culms showed reduction in growth and gave normally fertile spikes (see photograph). Presumably colchicine had passed from the treated culms to the untreated ones and acted on meiosis or on cells just before meiosis.

The original plant was produced by crossing 'Ardito' wheat ($2n = 42$) with 'Petkus' rye ($2n = 14$), and the appearance of the sterile spikes showed that it was a true hybrid. On this basis, the plants from the grains produced by the fertile spikes were expected to have 56 chromosomes. However, in two plants already counted, 42 chromosomes were found, and one of these plants which developed to maturity is identical with 'Ardito' wheat.



In order to explain these results, one would have to consider the remote possibility of the original 'plant' developing from two embryos, one of which would be a true hybrid and the other the result of a self-pollinated ovule. More probably, however, it appears that rye chromosomes were lost during the divisions under the action of colchicine. As confirmation of this is the fact that knobs, which are characteristic of rye chromosomes, were not observed.

Assuming that this explanation is correct, we are led to conclude that the derived wheat plant is completely homozygous since it has resulted from the duplication of a gametic set of chromosomes.

More extensive experiments are now being undertaken.

Photosensitized Oxidation of Alcohols

RECENT investigations of the photo-oxidation of alcohols, sensitized by benzophenone[1] and by azo-dyes[2], while providing valuable information regarding the general form of the reaction, do not enable its detailed mechanism to be specified. Using anthraquinonoid sensitizers, however, it has been possible to obtain diagnostic evidence as to the nature of the individual processes concerned.

Aqueous neutral or acid solutions of the alcohol containing small quantities (10^{-3}–10^{-4} M) of anthraquinone 2 : 6 disodium sulphonate were irradiated (λ c. 3650 A.) in presence of oxygen at a shaking speed of 600 cycles/min.

The chief features of the photosensitized oxidation of ethanol are:

(1) The rate of oxygen uptake at constant pressure is virtually independent of the reactant concentrations but is proportional to the first power of the rate of light absorption. Also the quantum yield is approximately unity and is independent of temperature (0–40° C.). Hence a non-chain mechanism is in operation.

(2) The reaction products consist simply of acetaldehyde, acetic acid and peroxide (almost entirely hydrogen peroxide). It has been demonstrated conclusively that, except at low alcohol concentrations, acetic acid arises directly from the ethanol; it is not the result of secondary oxidation of the acetaldehyde.

(3) Product yields based on the oxygen absorbed by the system are independent of light intensity and alcohol concentration, but vary significantly with oxygen pressure and sensitizer concentration. The limiting conditions are:

Oxygen pressure	Low	High
Sensitizer concentration	High	Low
Acid yield	0 per cent	55 per cent
Aldehyde yield	100 ,,	18 ,,
Peroxide yield	100 ,,	70 ,,

(4) The reaction-rate and product yields are independent of pH under non-alkaline conditions. This, together with other evidence, suggests that the photo-oxidation occurs by a free-radical mechanism.

(5) The anthraquinonoid sensitizer operates by a cyclic mechanism; its concentration remains unchanged after the absorption of many times the equivalent amount of oxygen. At low oxygen pressures, measurable quantities of the corresponding anthrahydroquinone are produced, indicating that the initial attack by the photo-excited sensitizer molecule involves abstraction of hydrogen from its surroundings. Since this does not occur in absence of the substrate, it follows that the hydrogen is removed from the alcohol, with the simultaneous production of a semi-quinone radical. At high oxygen pressure, this is rapidly re-oxidized to the anthraquinone form; at low oxygen pressure, further reduction to the anthrahydroquinone can occur.

These observations may all be interpreted in terms of the following reaction scheme:

$$\begin{array}{llll}
(1) & A & + h\nu & \rightarrow A^* \\
(2) & A^* & + RH & \rightarrow AH— + R— \\
(3) & R— & + O_2 & \rightarrow RO_2— \\
(4) & AH— & + O_2 & \rightarrow A + HO_2— \\
(5) & R— & + A & \rightarrow AH— + \text{aldehyde} \\
(6) & RO_2— & + RO_2— & \rightarrow 2\ \text{acid} + H_2O_2 \\
(7) & RO_2— & + HO_2— & \rightarrow \text{aldehyde} + H_2O_2 + O_2 \\
(8) & HO_2— & + HO_2— & \rightarrow H_2O_2 + O_2 \\
(9) & R— & + R— & \rightarrow \text{aldehyde} + RH \\
(10) & R— & + RO_2— & \rightarrow 2\ \text{aldehyde} + H_2O_2 \\
(11) & R— & + HO_2— & \rightarrow \text{aldehyde} + H_2O_2 \\
(12) & AH— & + AH— & \rightarrow AH_2 + A
\end{array}$$

RH represents the alcohol, R— the radical $R.\underset{\mathrm{OH}}{\overset{\mathrm{H}}{\mathrm{C}}}$—, while RO_2— corresponds to $R.\underset{\mathrm{OH}}{\overset{\mathrm{H}}{\mathrm{C}}}$—OO— and AH— to the semi-quinone radical. When acid production is favoured, reactions (1)–(4) and (6)–(8) predominate.

Applying stationary-state conditions to this scheme it can be shown that:

(a) To a first approximation over the whole range of oxygen pressure and sensitizer concentration:

$$\frac{1}{(\text{acid yield})^{1/2}} = C' + C'' \frac{[A]}{[O_2]},$$ where C' and C'' are constants.

(b) At high $[O_2]$ and low $[A]$:

Acid yield × 3/2 + aldehyde yield = 100 per cent.

Acid yield + aldehyde yield = peroxide yield.

(c) At low $[O_2]$ and high $[A]$: aldehyde yield = peroxide yield = 100 per cent.

The experimental data are in accordance with these relationships.

In many respects the above mechanism resembles those established for the autoxidation of unsaturated hydrocarbons[3] and aldehydes[4]. The completely different kinetic behaviour results from the fact that the peroxy-radicals are incapable of abstracting hydrogen from further alcohol molecules. Moreover, the products are derived almost entirely from the inter-radical terminating processes, which make only a minor contribution when reaction chains are being propagated. Hydroxy-hydroperoxide and hydroxy-peroxides do not figure significantly among the products because they readily break down to aldehyde and hydrogen peroxide.

Photo-oxidations conducted in absence of water using anthraquinone as sensitizer, and also in aqueous solution using hydrogen peroxide, agree with the above picture. Similar considerations have been applied to secondary alcohols and α-glycols. *iso*-Propanol, for example, gives the expected 100 per cent yields of acetone and hydrogen peroxide at all oxygen pressures and sensitizer concentrations; 2 : 3 butylene glycol, however, exhibits the additional feature of carbon-carbon bond fission.

This mechanism is of interest in connexion with the phototendering of cellulosic textiles, induced by certain anthraquinonoid vat dyes: it suggests how hydrogen peroxide[5] can arise and carbonyl groups can be introduced into the cellulose molecule. The latter, under the mild alkaline conditions of washing, are then sufficient to bring about degradative reactions of the type recognized by Davidson[7] and recently interpreted by Corbett, Kenner and Richards[8]. It is important to emphasize, however, that this represents only one aspect of the complex tendering process.

This work forms part of the programme of fundamental research being carried out by the British Rayon Research Association.

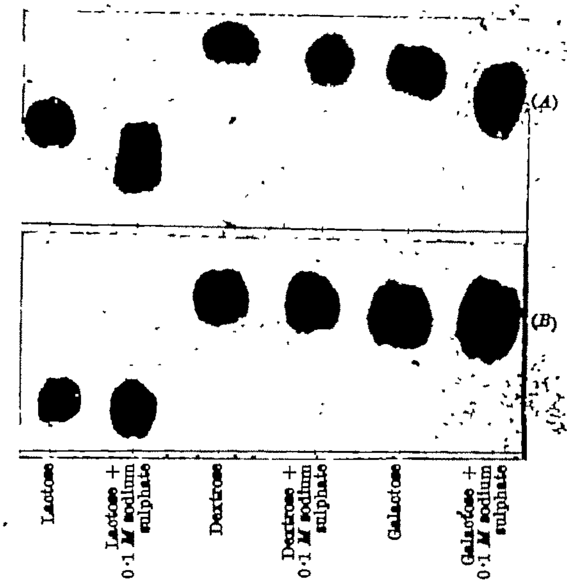
Salt Interference in Sugar Chromatography of Urine

During a recent investigation of lactosuria in burns[1] following cutaneous absorption of the lactose from penicillin-lactose powder, it was found that ascending chromatography of the urine yielded spots of considerably lower R_F values than lactose itself. 0·02 ml. amounts of urine were applied; and the solvent consisted of *n*-butanol 5·7 parts, ethanol 1·57 parts, water 2·73 parts, and contained 1 per cent ammonia solution. The substance obtained from these spots, however, when isolated and identified by standard chemical procedures, proved to be lactose.

Similar anomalous R_F values could be obtained using the organic phase of a solvent system consisting of *n*-butanol 4 parts, water 5 parts and glacial acetic acid 1 part. The spots when sprayed with aniline hydrogen phthalate or *p*-anisidine hydrochloride showed a lower, more intensely staining region. When 0·1 *M* sodium sulphate or sodium phosphate was substituted for urine, similar results were obtained. Sodium chloride (0·2 *M*) or 2 per cent urea used as lactose solvents did not give lowered R_F values.

R_F values almost corresponding to those of the reference substance in water were given in a neutral solvent system containing *n*-propanol 7 parts, ethyl acetate 1 part, and water 2 parts. We therefore inferred that the phenomenon observed could not be entirely explained by hydration.

To investigate the possibility of compound formation, as suggested by the more intensely stained region, 2 per cent lactose in 0·1 *M* sodium sulphate was run two-dimensionally using a neutral solvent for the second development. Only one spot of similar R_F to the reference spot was obtained. Serial elution after loading a cellulose column prepared from Whatman No. 4 paper with lactose in sodium sulphate showed lactose contaminated with salt and pure lactose. The salt-contaminated fractions, when freed from the salt, showed identity with pure lactose. It was therefore concluded that no compound or complex was formed with the salt.



(A)
(B)
Lactose
Lactose + 0·1 M sodium sulphate
Dextrose
Dextrose + 0·1 M sodium sulphate
Galactose
Galactose + 0·1 M sodium sulphate

Duplicate chromatograms of sugars with and without 0·1 *M* sodium sulphate run in (*A*) *n*-butanol/ethanol/water/ammonia, and (*B*) *n*-propanol/ethyl acetate/water

It is well known that organic acids will migrate in organic solvents either as the free acids or as their ammonium salts[2]. Definite though low R_F values are also given by inorganic acids and their salts. Duplicate chromatograms of lactose in sodium sulphate were run in *n*-butanol, ethanol and water containing ammonia. One was sprayed with bromophenol blue in 0·2 per cent aqueous citric acid. It was found that the darker-stained area shown when sprayed with aniline hydrogen phthalate corresponded to the upper region of the acid spot, which had migrated as its ammonium salt. The failure of sodium chloride to cause the interference is explained by its failure to migrate in the solvent system employed.

We also investigated whether the anomalous R_F values were produced by an initial delay only or by a persistent slowing throughout the run. Sugars of varying R_F values were chosen and the chromatograms run for 4, 6, 12 and 24 hours under identical conditions. The values show that the retardation is less marked the faster the sugar moves, but its relative magnitude is unaffected by time. This suggests that there is a persistent interference between the salt and the sugar causing a continuing elongation and fusion of the two spots in the case of slower-moving sugars.

Distance Travelled (mm. from Origin) by Sugars With and Without Sodium Sulphate
(*n*-butanol/ethanol/water/ammonia)

Time (hr.)	Lactose	Lactose in 0·1 *M* sod. sulph.	Maltose	Maltose in 0·1 *M* sod. sulph.	Galactose	Galactose in 0·1 *M* sod. sulph.	Dextrose	Dextrose in 0·1 *M* sod. sulph.
4	17	10	18	12	27	20	31	27
6	19	12	26	16	33	28	40	32
12	33	22	33	26	58	47	61	56
24	42	28	47	31	70	58	80	72

In view of this experience, it is suggested that sugar chromatograms of biological material which it might be impractical to de-salt should be run in a neutral medium. We have found the *n*-propanol/ethyl acetate/water mixture described above highly suitable for separation of reducing sugars occurring in biological fluids.

Slow-Neutron Scattering Cross-Sections of Magnesium

The bound-atom and the coherent scattering cross-sections of magnesium have been given[1] as 4·2 and 2·4 barns respectively, and it has been pointed out[2,3] that these values are inconsistent with later measurements. In order to decrease the margin of uncertainty, we have re-determined the free-atom scattering cross-section.

The total cross-section of magnesium has been measured using the arrangement shown in Fig. 1, which selects neutrons in the energy-range 0·5–1,000 eV. The number of neutrons scattered by the 2 gm./cm.^{2} of B_2O_3 or 0·070 in. of polythene is the same. Thus, if we denote the counting-rates with and without the sample when the polythene (boron) is in position by P_s (B_s) and P (B) respectively, the ratio $(P_s - B_s)/(P - B)$ will be the transmission of the sample for those neutrons which are absorbed by the 2 gm./cm.^{2} of B_2O_3. The calculated spectrum of these neutrons is shown in Fig. 2, and their calculated mean wave-length is 0·145 A. (3·9 eV.). Over the neutron energy-range covered by this spectrum, the absorption cross-section of magnesium is negligible[4] and the total cross-section is constant[4], so that our measurement is of the free-atom scattering cross-section.

Measurements were carried out with samples of magnesium metal and its oxide. The oxygen total cross-section[4] was subtracted from the magnesium oxide cross-section. The results obtained were 3·53 ± 0·14 and 3·49 ± 0·12 barns from the magnesium and magnesium oxide measurements respectively. The mean value is 3·51 ± 0·09 barns. This yields a calculated bound-atom scattering cross-section of 3·82 ± 0·10 barns compared to 3·8 ± 0·2 quoted in ref. 4.

The coherent scattering cross-section has been determined recently by the neutron diffraction[2] and the mirror[5] techniques, values of 3·4 ± 0·14 and 3·7 ± 0·15, respectively, being obtained. If the mean of these values is subtracted from our value for the bound-atom cross-section, a value of 0·27 ± 0·14 barn is obtained for the incoherent cross-section. This result is consistent with the direct measurements of Squires[3] (0·11 barn) and Egelstaff[6] (0·09 ± 0·02 barn) of the incoherent cross-section. Thus the values of the scattering cross-sections of magnesium are now in better agreement.

Photo-elastic Effect in Lead Nitrate

In an earlier communication[1], it was reported that barium nitrate behaves in an exceptional manner in respect of its photo-elasticity. Since then, crystals of lead nitrate have also been studied, and differences between the stress-optical constants, as determined by a Babinet compensator for the sodium D lines, are found to be:

$$(q_{11} - q_{12}) = -19{\cdot}13 \times 10^{-13}, (q_{11} - q_{13}) = -11{\cdot}84 \times 10^{-13} \text{ and } q_{44} = -1{\cdot}393 \times 10^{-13} \text{ c.g.s. units.}$$

These values are similar to those obtained in barium nitrate in being quite large. $(q_{11} - q_{12})$ is different from $(q_{11} - q_{13})$, as we should expect for the T_h class of crystals to which lead nitrate belongs. The difference is 60 per cent of the lower value and is very large indeed. As in barium nitrate, in this substance also, the birefringence produced by pressure along a cube axis is nearly fourteen times that produced by an equal pressure along a cube diagonal. The photo-elastic behaviour of lead nitrate is therefore to be regarded as highly anisotropic and very exceptional.

FORTHCOMING EVENTS

(*Meetings marked with an asterisk * are open to the public*)

Tuesday, September 1—Wednesday, September 2

International Joint Commission on Oceanography (in the Jane Herdman Geology Laboratories, University of Liverpool, Brownlow Street, Liverpool), at 10 a.m. each day.—Symposium on "The Deep Sea Floor and the History of the Earth".

Wednesday, September 2—Wednesday, September 9

British Association for the Advancement of Science (at Liverpool).—Annual Meeting:

Wednesday, September 2

At 8.30 p.m.—Sir Edward Appleton, F.R.S.: "Science for its Own Sake" (Presidential Address).

Thursday, September 3

At 10 a.m.—Sir Edward Appleton, F.R.S.: "Finding Things Out with Radio and Rockets" (Junior Presidential Address).

At 10 a.m.—Prof. G. R. Clemo, F.R.S.: "A Suggestion and Some Consequences" (Presidential Address, Section B).

At 10 a.m.—Prof. J. E. Smith: "The Maintenance and Spread of Sea-shore Faunas" (Presidential Address, Section D).

At 10 a.m.—The Rt. Hon. Lord Dudley Gordon: "Engineering in the Next Two Thousand Years" (Presidential Address, Section G).

At 10 a.m.—Prof. J. Walton: "The Evolution of the Ovule in the Pteridosperms" (Presidential Address, Section K).

At 12 noon.—Prof. D. W. Harding: "Psychological Problems in the Recognition of Excellence" (Presidential Address, Section J).

At 2.30 p.m.—Dr. W. E. Swinton: "Gateways of Science" (Presidential Address, Section X).

Friday, September 4

At 10 a.m.—Prof. Sir Harold Jeffreys, F.R.S.: "Half a Century of Geophysics" (Presidential Address, Section A).

At 10 a.m.—Prof. R. H. Kinvig: "The Geographer as Humanist" (Presidential Address, Section E).

At 10 a.m.—Prof. F. W. Paish: "Open and Repressed Monetary Inflation" (Presidential Address, Section F).

At 10 a.m.—Prof. M. Fortes: "Analysis and Description in Social Anthropology" (Presidential Address, Section H).

At 10 a.m.—Mr. Robert Birley: "Greek or Chemistry or Both"? (Presidential Address, Section L).

At 10 a.m.—Dr. J. Hammond, F.R.S.: "Applications of Animal Physiology to Agriculture" (Presidential Address, Section M)

At 8 p.m.—Sir Ben Lockspeiser, F.R.S.: "Fifty Years of Powered Flight".

Monday, September 7

At 10 a.m.—Prof. T. Neville George: "Invertebrate Fossils and Evolution" (Presidential Address, Section C).

At 10 a.m.—Dr. D. P. Cuthbertson: "Quality and Quantity of Protein for Man and Livestock" (Presidential Address, Section I).

At 8 p.m.—Mr. Eric Shipton: "Mount Everest".

Wednesday, September 2—Saturday, September 12

National Radio and Television Exhibition (at Earls Court, London, S.W.5).*

Thursday, September 3—Thursday, September 17

Chemical Plant Exhibition (at Olympia, London, W.14).*

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Chemist (with good honours degree or equivalent professional qualification, and preferably two or three years general experience in industrial laboratories) at the Central Laboratory, Chiswick—The Staff Officer (F/EV247), London Transport, 55 Broadway, London, S.W.1 (September 5).

Civil Engineer (preferably Corporate Member of the Institution of Civil Engineers) in the Generation Construction Department—The Director of Establishments, British Electricity Authority, Winsley Street, London, W.1, quoting AE/406 (September 5).

Senior Scientific Officer (with good honours degree in botany or agricultural botany and research experience in genetics and/or plant breeding) and a Scientific Officer (with good honours degree in botany or agricultural botany) in the Grass Breeding Section—The Registrar, Welsh Plant Breeding Station, University College of Wales, Aberystwyth (September 5).

Assistant, male (with sound training in laboratory methods, both physical and chemical, and preferably with experience in biological work), for work on the development of storage techniques for fruit—The Secretary, East Malling Research Station, Maidstone, Kent (September 7).

Physiologist (preferably with neurophysiological experience) in the Department of Applied Electro-Physiology for duties which will include the supervision and interpretation of EEGs, EMGs, and other electro-clinical investigations, and research in these and related subjects, on human and animal material—The Secretary, The National Hospital, Queen Square, London, W.C.1 (September 7).

Assistant Experimental Officer or Experimental Officer at the Agricultural Research Council Plant Virus Research Unit, Cambridge, to work on insect virus diseases—The Secretary, Agricultural Research Council, Cunard Building, 15 Regent Street, London, S.W.1 (September 8).

Demonstrator in Electrical Engineering and Physics (with degree or equivalent qualification, and preferably with industrial experience) to assist in organization, preparation and control of work in electrical and physics laboratories—The Principal, Royal Aircraft Establishment Technical College, Farnborough (September 8).

Research Assistant (with good honours degree in chemistry) in the Department of Chemistry—The Professor of Chemistry, Royal Holloway College, Englefield Green, Surrey (September 14).

Assistant Lecturer (with special interests in research into child psychology) in the Department of Psychology, and a Research Assistant to carry out experimental work under the Professor of Psychology—The Registrar, The University, Manchester 13 (September 15).

Assistant Lecturer (Grade III) or Lecturer (Grade II) in Inorganic Chemistry—The Registrar, The University, Bristol (September 16).

Chemists (with good honours degree or equivalent) in the Coal Survey Laboratories at Cardiff and Chester, to undertake analytical and investigational work—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, quoting TT/677 (September 19)

Lecturer or Assistant Lecturer in Chemistry (with special interest in inorganic or analytical chemistry)—The Registrar, The University, Sheffield (September 19).

Research Officer (with university honours in agricultural science, or a degree with postgraduate research experience; or an honours degree in science, with agricultural training and experience) in the Commonwealth Scientific and Industrial Research Organization, Land Research and Regional Survey Section, Canberra, to participate in investigations concerning land use potentialities of undeveloped regions of the Commonwealth and to assist in preliminary surveys for special purposes—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting 570/26 (September 19).

Senior Research Officer or Research Officer (with honours degree in agriculture or science, and experience in research in plant nutrition) to carry out investigations into plant nutrition and biological problems, with particular reference to the cultivation of fruit trees, including citrus (Ref. No. 500/65); Senior Research Officer or Research Officer (chemist) (with honours degree in science or agricultural science or equivalent qualifications, and preferably with research experience in soil chemistry) to conduct research into various chemical aspects of plant growth and soil problems (Ref. No. 500/66), at the Commonwealth Scientific and Industrial Research Organization Irrigation Research Station, Griffith, New South Wales, Australia—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting appropriate Ref. No. (September 19).

Director (with high qualifications in agriculture or in one of the agricultural sciences, and with proved administrative ability, preferably with experience of tropical agriculture) of an Agricultural Research and Training Institute in Burma; which is to be established for the improvement of Burmese agriculture by applied research and education—The Burmese Embassy, 19A Charles Street, London, W.1 (September 22).

Director (with high qualifications in veterinary science and proved administrative ability and preferably with experience in tropical veterinary medicine) of a Veterinary Research and Training Institute in Burma, which is to be established for the improvement of Burmese livestock by applied research and education—The Burmese Embassy, 19A Charles Street, London, W.1 (September 22).

Lecturer (preferably with a medical qualification and some experience in protozoology) in the Department of Parasitology to carry out teaching and research work under the direction of the Head of the Department—The Dean, London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1 (October 1).

Lecturer in Clinical Chemistry—The Secretary, The University, Aberdeen (October 15).

Chemist (with good honours degree in chemistry and an ability to study agronomic problems and with knowledge of soil chemistry and physics) at the Sugarcane Research Station, Mauritius—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting 27106/37.

Lecturer or Assistant Lecturer in the Department of Electronics—The Secretary and Registrar, The University, Southampton.

Physicist (with first- or second-class honours degree in science, and preferably five years experience as a hospital physicist) in the Medical Department of Hong Kong—The Director of Recruitment, (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting CDE.117/51/013.

Physicists, Mathematicians and Engineers (Scientific Officer, Experimental Officer and Assistant Experimental Officer grades) at the National Aeronautical Establishment, Bedford—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A 209/53A.

The natural radioelements

- RADIUM ★
- RADON
- RADIUM D
- POLONIUM
- MESOTHORIUM
- RADIOTHORIUM
- THORIUM X
- THORIUM B

Even in these days of man-made isotopes the historical natural radioactive elements are still indispensable to the physicist, the radiotherapist and the technologist in industry. Here at the Radiochemical Centre we have a long experience of these materials and are now applying to their production many of the new techniques developed in connection with pile-produced isotopes. Thus we are able to supply the natural radioelements in a purer state and a wider range of physical forms than ever before.

as α-emitters, as β-emitters
as γ-emitters, as neutron sources,
as emanating sources

★ (*Appliances containing over* 1 *mg. of radium are supplied to United Kingdom institutions only on loan. For owners or suppliers of radium elsewhere we supply appliances and undertake their loading. We also recover radium from old appliances.*)

For further information please write to:—

THE RADIOCHEMICAL CENTRE, AMERSHAM, BUCKINGHAMSHIRE, ENGLAND

THE INTRINSIC VALUE OF SCIENCE

IN his presidential address to the British Association at Liverpool thirty years ago, Sir Ernest Rutherford, as he then was, surveying the rapid advance of physics since the Association had previously met in Liverpool—a period which had been termed the heroic age of physical science and which Sir Ernest himself was inclined to characterize as the renaissance of physics—made two points which are reflected in the address which his successor in the presidential chair has this year delivered to the Association (see p. 424 of this issue). Sir Ernest Rutherford noted, first, how the remarkable achievements in applied science which he reviewed had been built on the foundations laid by fundamental investigations of workers in pure science, but that these practical applications, in turn, had benefited the fundamental investigator by providing, through the new methods and appliances developed for technical purposes, the means of attacking still more difficult problems. No sharp distinction, said Rutherford, could be drawn between the importance of so-called pure and applied research : both were equally essential to progress, and, without flourishing schools of fundamental research in our universities and scientific institutions, technical research must tend to wither.

Sir Edward Appleton this year once again referred to the achievements of applied science and to the extent to which discoveries in pure science which, in their time, had no obviously practical import, had later proved to be the foundations of major improvements in our material civilization. While, however, he fully recognized the importance of this aspect of science, and that the cost of scientific research was part of the price to be paid for industrial progress, Sir Edward's fascinating exposition of the way in which during the past twenty years or more science has been exploring the mysteries of space was designed to illustrate not the practical value of science but its intrinsic value—that science is illuminating as well as fruitful. He developed a line of thought which can be seen in embryo in the closing paragraphs of his predecessor's address thirty years before.

Sir Ernest Rutherford said that the rapidity of advance in physics had impressed him more and more with the power of the scientific method in extending our knowledge of Nature, and he referred particularly to the importance of a happy blend of experiment and disciplined imagination, especially in a group of individuals of varied mental outlook. In penetrating obscurity we depended above all on the combined efforts of a number of adequately trained ordinary men of scientific imagination. The passage in which Rutherford elaborated the way in which the work of different specialists interacts and co-operation leads to general advance is a remarkable prediction of experience which, for example, operational research has made familiar ; and he referred in concluding to the importance of the intellectual value of scientific work, more especially as providing the intellectual appeal which would attract young men of ability to enter on a scientific career.

Sir Edward Appleton's address, by and large, takes up the theme where Rutherford left it. Leaving on one side for once the utilitarian aspect of science, he expounded brilliantly its intellectual interest, the way in which knowledge and insight supply sufficient reward in themselves and their pursuit provides a satisfying and worthy way of life. He also left on one side any consideration of the cultural or educational value of science; but nevertheless his address provides an outstanding demonstration of those inherent possibilities in science which could be used as vehicles of broad training not inferior in cultural value to the humanities. Quite incidentally, Sir Edward has taken up the theme which the late Sir Richard Gregory was never tired of urging, and has given a notable exposition of the value of science "as one of the great human endeavours to be ranked with arts and religion as the guide and expression of man's fearless quest for truth".

Moreover, it will be noted that, in pointing to the intrinsic value of science itself, Sir Edward did not attempt to claim that science by itself will supply all that is required for a full and complete life. Accordingly, his argument that science, when pursued for its own sake can, and does, provide an essential element in a satisfying life in the world to-day is the more convincing. He puts science in its right place, not simply as a means of doing things, of gaining power over Nature, of winning new knowledge, but as something by which man is enabled to live in a full sense. The passionate desire to explore and understand contributes something to the scientist who experiences it, whether he be amateur or professional, and quite apart from any achievements to which it may lead; and that contribution is just as enriching in its way to human life and experience as the immortal creations of the human spirit in poetry, art or religion, on which science as such has little light to throw.

In directing attention to the value of science as human experience and as a worthy means of expression for the human spirit, Sir Edward illustrated his argument by describing the way in which recent discoveries of great astronomical interest have been advanced at times by the observations of gifted and enthusiastic amateurs, even if the full meaning and implication of the observations had only been revealed by the skill of the professional scientist. In doing this he emphasized a value of science which was well brought out by Dr. C. E. Raven in his study of English naturalists from Neckam to Ray. Dr. Raven holds that Bacon and those Christian thinkers who followed him and founded the Royal Society were not primarily concerned with the benefit of their discoveries to mankind. Their basic conviction was that a more accurate understanding of the Creation would give them a truer knowledge of the Creator's will and thus enable men to live more fully and intelligently in accordance with that will.

Sir Edward Appleton's argument is, if we accept Dr. Raven's interpretation, essentially for the same point of view—that the scientific method of observation and experiment, and the qualities demanded in their pursuit, contribute to an outlook and a view of life that are both worthy and essential if men are to confront the world with understanding and unafraid. So far from reducing life to something cold and mechanical, modern science in its explorations ranges from the heart of the atom to the frontiers of the universe and, like poetry, reveals depths and mysteries beyond and quite different from the ordinary matter-of-fact world to which we are accustomed. Boldly, but with reason, Sir Edward claims that science has given back to the universe that quality of inexhaustible richness, unexpectedness and wonder which at one time it seemed to have taken away.

"Le silence éternel de ces espaces infinis m'effraie", wrote Pascal, and so might a contemporary Elizabethan write of the vastness of the universe being explored to-day, or of the possibilities disclosed by the discovery and application of nuclear fission and other discoveries and developments of our day. But, on reflexion, Pascal added: "Toute notre dignité consiste donc en la pensée. C'est de là qu'il faut nous relever et non de l'espace et de la durée, que nous ne saurions remplir"*. The contribution of science to the understanding of the forces of the universe is an essential element in the formation of a worthy and adequate view of life. Without it man can neither know, nor do, nor steer onward to any proposed haven.

The scientific approach is not only an essential element in the formation of a worth-while view of life; it is also, Sir Edward reminded us, a far more personal and imaginative activity than is sometimes realized. When all allowance is made for the distance that deliberate application to discovery can take us or for the progress which can result from team-work, especially in following up or consolidating a big discovery, the big jumps ahead are usually the adventures and intuitions of a single mind.

That scientific advance still depends so largely on the individual needs emphasizing in a world in which it is common to discount individuality and to foster uniformity, if not conformity. Sir Edward Appleton, however, was concerned to emphasize the extent to which the scientific process requires the fullest and subtlest employment of all our faculties rather than to urge that if the individual is to make his full contribution in science as in art, literature or other creative work he must find the conditions appropriate to creative expression. Many a vital discovery, he remarked, has been nothing else than recognizing the unexpected. Even in experimental work, it was the primacy of an imaginative idea or intuition that often started it all off, and whether like Pasteur we emphasize that chance only visits the prepared mind or, with Sir Edward, stress the importance of asking Nature the right question and in its most direct form, the rigour of the intellectual discipline involved is unmistakable.

A further point was brought out here by Sir Edward. Asking Nature the right question in the right way, or recognizing a theoretical pattern in a tangled skein of experimental data, often has the effect of introducing an element of beauty and elegance into the scientist's work. As he pointed out, when we refer to a "beautiful theory" or an "elegant experiment", we do not mean that the experiment is necessarily conclusive, or that the theory is irrefutable or even particularly fertile in its consequences. Rather we mean that it possesses a quality of inevitability—as if it could not have been done or expressed differently without losing something essential. Exactly the most appropriate means had been chosen, and the consequent economy of means or material or of words gives the experiment or theory something of the same character of fitness for the purpose that marks the choice and selection of the artist, sculptor or writer in the production of a great work of art.

---

* "Pensées", 206 and 347 (edit. Brunschvicg, Paris).

More might well be made of this imaginative aspect of science in relation to its creative faculty. "Reason", wrote Shelley, in his "Defence of Poetry", "is the enumeration of qualities already known; imagination is the perception of the value of those qualities, both separately and as a whole. Reason respects the differences and imagination the similitudes of things." Thus to cultivate the use of the imagination in science may both help to counteract the danger inherent in the analytical aspect of science, and simultaneously foster the creative powers on which real scientific advance always depends and the full value of science as a great human endeavour. Shelley's lament that "man having enslaved the elements, remains himself a slave", would then begin to lose much of its force.

Sir Edward did not go beyond claiming, first, that the scientist's approach to Nature demands mental qualities and awareness that make science in itself a worthy pursuit, and one capable of enriching personal life and giving real satisfactions; and secondly, that the skilful exercise of those qualities not only has values that amply justify a scientific vocation but also can on occasion rank with the discrimination exercised by a great artist. He forbore more than a mention of other personal qualities, greatly needed n the world at large to-day, which a scientific vocation tends to develop and which deserve to be ecognized and honoured. Sir Edward referred to he tolerance and open-mindedness to new ideas which shone from Rutherford's presidential address o the Association, and which all who knew him ecognized as characteristic of the man. He could qually have quoted that passage in Thomas Huxley's etter to Charles Kingsley which has brought inspiraion to thousands of scientists, amateur and proessional, and to many others who have sought to penetrate the mysteries of life: "Sit down before act as a little child, be prepared to give up every reconceived notion, follow humbly wherever and to whatever abysses Nature leads, or you shall learn othing."

These and other qualities are no monopoly of the cientist, though he can justly claim that their development is fostered by a scientific vocation, for ne practice of which they are essential. If therefore cientists do well to heed Sir Edward's warning and ndeavour to see themselves as others see them, in heir weaknesses and limitations as well as in their rength and excellence, there is at least this to be membered—that in urging that it is to the interest of the community to see that the scientist enjoys the conditions in which he can most effectively pursue his search for truth, we are no more than pleading for the conditions in which all man's most creative work has been done in art and literature, in philosophy, in religion and in science.

To secure or even to re-establish those conditions is a task demanding constant vigilance to-day, and if science is to be pursued for its own sake and enlarge men's horizons and invest the world with deeper significance, that task cannot be neglected. The history of science can furnish examples enough of discoveries and advances delayed because the climate of opinion was unfavourable. To press that point, however, is to return to the pragmatic approach which Sir Edward specifically eschewed. Furthermore, while as a mental discipline science is one of the most complex and far-ranging of our mental experiences, it is only one of those experiences, and one among other values. Sir Edward stressed—and rightly—the imaginative function in science: there is also, and no less important, the analytical function, and these two, if not incompatible, are not easily kept in balance.

This is doubtless one reason why it has been said that the chief limitation of natural science is that it is not human. Without, however, admitting that that is entirely true, it is wise to recognize that the analytical element in science imposes clear limits on the contribution which science by itself can make to the full development of human personality. At the opposite pole from scientific endeavour are ways of thought which do not change and are concerned with what is not new—with things which will not be superseded. Science indeed teaches men not to be afraid of change, but to-day, as Sir Edward Appleton suggested, we need these enduring and sustaining values of the spirit more than ever. In our constant urge to seek fresh truths and new understandings, only too easily do we lose sight of other aspects and values of life, and Sir Edward fitly crowned his brilliant interpretation of the intrinsic value of science with this insistence that it is only one among other and equally great values of human experience.

Scientists may, as he said, be fortunate in that their vocation is, by its very nature, dedication to an end, and they need never lack the opportunity for dedication. But we must admit that the striving of the scientist and his pursuit of virtue and knowledge will not provide the complete human satisfaction unless it is matched by those other great human values to which Sir Edward alluded. In its different setting, the pursuit of science presents to the human mind an enduring challenge on an endless frontier, typified in the challenge which Everest, the Arctic and the Antarctic have presented, and quite apart from any incidental material benefit to mankind. "It is the adventurous spirit which all scientific men need in their pursuits", wrote Sir Francis Younghusband. "The human race will never be satisfied until it has completed its knowledge of its surroundings."

It is not simply, however, for this testimony to the cultural and human value of science that Sir Edward's address is so welcome. A. N. Whitehead has pointed out how much the development of science has owed to the antecedent generation of faith in the possibility of science as an unconscious derivation from medieval theology. Mill pressed home a like argument when he insisted that unless an elementary knowledge of science was diffused among the public, they never knew what was certain and what was not, and either had no faith at all in the testimony of science or were the ready dupes of charlatans. Sir Edward's plea for science for its own sake should stimulate fresh and constructive thought on the teaching of science and training of scientists, and especially on the use of science as a vehicle of liberal education. It should equally encourage the pursuit of science for its own sake, by the amateur as well as the professional; this could go far to promote a public understanding which in these days is increasingly essential, both to ensure adequate public support and to secure the conditions in which scientific investigation is most fruitful.

MERSEYSIDE

A Scientific Survey of Merseyside

Edited by Prof. Wilfred Smith, assisted by F. J. Monkhouse and H. R. Wilkinson. Pp. xv+299+8 plates. (Liverpool: Published for the British Association by the University Press of Liverpool, 1953.) n.p.

THE British Association is to be congratulated in having brought out ten days in advance of its meeting in Liverpool a "Scientific Survey of Merseyside": no member attending this year's meeting can afford not to study this handbook for the background knowledge that it gives if he wants to make full use of his stay in Liverpool. The book follows the same lines as those of previous years in being not only a scientific but also a historical, sociological and, in general, cultural review of the district. It is composed of three parts, each roughly a hundred pages long, devoted respectively to the "Land and the Sea", "Merseyside" and "Merseyside District", and each part contains about ten separate articles written by experts in the particular fields. The co-ordinating editor is the John Rankin professor of geography in the University of Liverpool, and the two assistant editors are also in the Department of Geography of the University. It can be said of this book, and rightly so, that the method of compilation is fragmentary, with inevitably some overlap between the fragments, but it can equally be said that the multiplicity of authorship ensures that each section bears the stamp of authority; also, since the volume is produced primarily for the members of the British Association, whose interests are indeed manifold, any one member can find in this book a succinct account of the aspect of Liverpool that appeals to him most, and the rest of the book can be read more casually. Anyway, the fact that the Association always produces this type of handbook in this particular way must surely be proof that it is the method which its members prefer.

Being specialized, the articles are varied in content and approach, but one feature runs right throughout a large number of them: the development of the district has been essentially coastal and, more especially, has been built up around the estuaries of first the Dee and afterwards the Mersey. The history of England is very much the history of its coasts, and it has often happened that important ports were developed which in later years silted up and lost their pre-eminence to another, often lesser, port that was more favourably situated. So too, from the days of the Roman occupation until the Middle Ages, Chester was the great town for the area and the Dee was the source of its strength. By contrast, the Mersey was a large dangerous river, unsheltered and with strong tidal currents, and Liverpool was a hamlet of no consequence, the first mention of its name "Liverpul" (the etymological derivation of which is uncertain) being in an undated charter of about 1190. As the Dee silted up, attempts were made to establish harbours downstream of Chester, but of no avail, and to-day Chester's maritime greatness merely survives in the tradition that its Mayor holds the office of Admiral of the Dee and his symbol is an oar.

Liverpool's population grew from approximately 5,000 in 1700 to 20,000 in 1750 and 53,853 in 1790, this last figure being determined by an official 'scrutiny'. The increase continued unchecked throughout the nineteenth century so that by 1931 the four county boroughs of Merseyside—Liverpool, Bootle, Birkenhead and Wallasey—had a total population of 1,183,000 with 208,000 in the surrounding districts. The very great concentration of inhabitants probably represents a peak, for in 1951 the corresponding figures were 1,108,000 and 359,000, respectively. The decrease in the central population was mainly experienced by Liverpool itself, which had 62 per cent of the total in 1931 but only 54 per cent in 1951; thus there has been a general trend away from the crowded centre, a trend which was materially accelerated by the bombing during the Second World War and the subsequent rehousing of the people in new estates built outside the city boundaries.

It is the aspect of its population which makes Merseyside a fascinating study for the sociologist, and the scientist and historian as well—the phoneticist alone has a rich field, as anyone who has listened to "Frisby Dike" on the B.B.C. will readily acknowledge. A number of the articles of the handbook, each well furnished with statistics and diagrams showing geographical distribution, discuss the multiplicity of race; and a feature that is very apparent is th strong connexion that Merseyside has with the peopl living in the comparatively narrow fringe along th northern coast of Wales from the Dee to well-nigh the tip of Caernarvonshire.

Of the rest of the contents of the book, spac precludes but a mere mention of one or two points Thus there are descriptions of how the Mersey becam a suitable harbour by the creation of docks, the firs one being opened in 1715, and how, with the comin of steam, the ferry services improved, leading to th growth of Birkenhead and Wallasey. Then there i the mineral wealth of the country—the salt deposit of Cheshire and, more important, the coal mine linking up with the great industries of Lancashire again, the advent of steam, in this case in the pumping of the mines and later in the development o railways (witness the famous Liverpool–Mancheste line) ensured that Liverpool would be an outlet for great industrial hinterland. Finally, there is th University of Liverpool itself, which this yea celebrates its jubilee; it is fitting that the Britis

Association should meet this year in the precincts of an institution which, for fifty years as university and for long before that as a university college, has been in the forefront of science and learning of all kinds.

MILNE ON JEANS

Sir James Jeans

A Biography. By the late E. A. Milne; with a Memoir by S. C. Roberts. Pp. xvi+176+2 plates. (Cambridge: At the University Press, 1952.) 21*s*. net.

The Syndics of the Cambridge University Press, which had published most of the books, both technical and popular, written by Sir James Jeans, wished after his death to publish a biography of him. In consultation with Jeans's executors—of whom one was then secretary of the Press (Mr. S. C. Roberts, now Master of Pembroke College, Cambridge)—Prof. E. A. Milne was invited to write the book, and agreed on condition that his should be the final voice on any question as to its contents that might arise between him and the Syndics or executors.

Milne finished the book some months before his own untimely death in 1950. It is of moderate length, and is almost equally divided between six biographical chapters and six dealing in some detail with Jeans's varied achievements. There is also a bibliography (and a somewhat faulty index) and two excellent photographs of Jeans in middle life—more photographs at other ages would have been welcomed by many readers.

Eddington, though younger, died before Jeans, in 1944. He, Jeans and Milne engaged in notable scientific controversies at the Royal Astronomical Society. In these debates there was all-round mutual criticism; but on the whole Milne sided with Jeans. To the end they differed on the disputed scientific points, but remained on terms of personal courtesy and recognized the greatness of each other's achievements.

Their controversies have echoes in this book, and, as in the life-times of the three men, other scientists may differ from Milne's judgments on parts of Jeans's work—and, incidentally, of Eddington's. The scientific half of this biography is in some places necessarily highly technical, and a section of the large public to which Jeans's popular writings appealed will find themselves at times out of their depth in reading it. But they may also enjoy many passages in it, for Milne himself had a clear, and often vivid, style—though he did not follow Eddington and Jeans in writing for the general educated public.

His scientific appraisal of Jeans's work begins with Chapter 7, on the state of physics in Jeans's boyhood, and proceeds to chapters on five divisions of his work: first on the partition of energy between different wave-lengths, in the radiation from a 'black' body—in this field Jeans derived anew, and corrected, an important formula given by Rayleigh. This work exposed, without solving, the difficulties that were met by the development of the quantum theory. Mention might have been made in this chapter of Jeans's contribution to the older type of kinetic theory of non-uniform gases, in which, by considering the persistence of molecular velocities after collisions, he improved the calculation of the coefficients of viscosity, conduction and diffusion.

Then follow two admirable chapters on the forms of equilibrium of rotating fluid masses, and on the dynamics of star clusters, which describe some of Jeans's most permanent and valuable achievements. The next chapter, on the internal equilibrium of the stars, is valuable but in several points debatable. The final chapter gives a decidedly critical summary of Jeans's incursions into philosophy.

The first six biographical chapters are easier to read and also of great interest. The first describes Jeans's early life, at school and college; his college career was interrupted by a serious illness which took him for more than two years to a sanatorium, where he wrote his original and successful book "The Dynamical Theory of Gases". The second chapter deals with his four years at Princeton, including his first marriage; and the third with the years 1909–19, spent at Cambridge, Guildford, London, and (from 1918) at Cleveland Lodge, Dorking, where he installed an organ for his own use, and where he lived thereafter, except for a time during the Second World War. Chapter 4 covers the decade to 1929, in which he exerted much influence as secretary of the Royal Society, while still continuing his scientific researches, one main fruit of which was his recognition of radiative viscosity. Chapter 5 relates how he was led to turn from research to popular exposition, which brought him widespread fame and added wealth. The last fifteen years of his life occupy Chapter 6; the loss of his much-loved first wife, and the illness of their only child Olivia (who did not long survive her father), sadly beclouded his seemingly bright fortunes.

In these biographical chapters Milne attempted no account of Jeans's complex and interesting personality. Unlike some men who devote themselves to deep and difficult researches, Jeans was no recluse; he mixed freely and widely with his fellow scientists, and was a good man of business, yet he was shy and lonely. He showed many personal kindnesses, and enjoyed appreciation and friendliness from his colleagues and others; but he found it very difficult to disclose his deeper feelings and allow intimacy to grow. The book is therefore much enriched by the seven-page "memoir" in which Mr. Roberts describes how friendship developed between him and Jeans after the death of the first Lady Jeans; and of how, a few years later, this aloof, constrained 58-year-old widower, through his love of music, won a charming young wife, and renewed happiness in a marriage blessed with the family cares and companionship of three young children. SYDNEY CHAPMAN

SIR EDWIN CHADWICK, THE SOCIAL REFORMER

The Life and Times of Sir Edwin Chadwick

By Prof. S. E. Finer. Pp. xi+556. (London: Methuen and Co., Ltd., 1952.) 42*s*. net.

This clearly written book can be recommended to all who are interested either in the social or administrative history of England and to those who wish to know more about the early struggles of social scientists in Great Britain. So far as historians are concerned, the value of the book is obvious, for the development of the social services, and of the administrative institutions connected with them, is a most important aspect of English nineteenth-century history. The capitalist phase of the English industrial revolution cannot be properly understood without a detailed knowledge of the organization of the 'poor law', and the slow growth of the public health services. Edwin Chadwick was so much involved in their development that the history of social administration in the two middle quarters of the nineteenth century is largely the story of his public life. The relevant material has been assembled with great care by Prof. S. E. Finer and analysed with skill. As a result, the story he recounts of important events such as the "Andover Scandal" will be read with pleasure as well as with profit, for it throws much light on the underlying political and social trends of the times, and it is also a complete human drama in itself.

Even more important, however, Prof. Finer's book can be regarded as a case-study in the most important field of the relationship between social structure, individual behaviour and technological change. The opening chapters of the book describe the ways in which the scientific techniques of the day were applied to the study of social problems and the consequences that followed from the personal and emotional involvement of a number of important individuals in the complicated social processes of 'poor law' reform. Chadwick is shown to be a clear-thinking man of action, whose somewhat naïve endeavours seem almost to have been calculated to arouse the greatest degree of opposition in whatever situation he was placed. This remarkable phenomenon became even more plain when he was forced out of 'poor law' administration and entered that of public health. He was usually right; but the more the facts were on his side and the more reasonable his interpretation of them was, the greater the degree of resistance he encountered. His battle with the sanitary engineers on the issue of the self-cleansing earthenware pipe versus the man-sized brick sewer may well turn out to be a classic example of the folly of endeavouring to change a situation in which the lives and the interests of many intelligent and experienced people are deeply involved, by a frontal attack merely designed to demonstrate the unsoundness of their views.

Social scientists and administrators have moved a long way since Chadwick's day, but his example and experiences are still of significance to the practitioner as well as the student.

MINERAL NUTRITION OF PLANTS

Mineralstoffe und Pflanzenwachstum

Von Prof. Dr. Walter Baumeister. Pp. viii+176. (Jena: Gustav Fischer, 1952.) 12 D. marks.

ALTHOUGH the processes involved in the organic and in the inorganic nutrition of plants are closely related and interconnected, they are often, and indeed usually, considered as separate aspects of the physiology of plants. This is very understandable and reasonable, for the methods used to examine the problems of the assimilation of carbon into the plant from the air are generally quite different from those that have been evolved for the investigation of the absorption of the mineral constituents of the plant from the soil and the fate and function of these constituents in the plant.

As a result of the vast amount of work which has been published on the mineral nutrition of plants since Liebig, working in the latter part of the first half of the nineteenth century, laid the foundations of our knowledge of the subject, we now have a considerable, if still inadequate, mass of information on the processes concerned in mineral nutrition. It is therefore rather surprising that only a very few attempts have been made to present a general view of the inorganic nutrition of plants. Prof. W. Baumeister's attempt to do this is therefore all the more welcome.

After a brief historical review of the subject, there follows a section on the significance of the mineral elements for the plant. This indeed takes up more than 90 per cent of the whole work; the succeeding sections on the significance of soil reaction for the distribution of plants, the physiological significance of the elements and their position in the periodic system, and the maintenance of nutrients in the soil and harvest yield, together occupy only eight pages.

The main section of the book opens with an account of methods, including descriptions of the water-culture and sand-culture methods and field-trial techniques. These are on the whole satisfactory, but one must take exception to the unqualified statement that aeration of water cultures is generally not necessary for higher plants. While it is true that plants of many species will survive in unaerated water cultures, it has been known for many years that lack of aeration may affect very adversely the rate of growth of plants of many species in water culture.

The facts and theories of the absorption of mineral constituents by the roots are usefully and succinctly dealt with, and there is a very brief summary of the mineral content of different kinds of soil and a longer account of the mineral content of plants. The parts played by the individual mineral elements, including nitrogen and the trace elements, are considered in much more detail. Here the ground is on the whole well covered, although there are a few rather surprising omissions. Thus, in dealing with the physiological significance of copper there is no mention of the copper enzymes, nor is there any reference to the presence of zinc in the enzyme carbonic anhydrase. However, in spite of these omissions, the book presents a balanced and reasonably concise review of the subject of the mineral nutrition of plants and should prove useful for students of plant physiology.

W. Stiles

HUMAN ECOLOGY

Les fondements de la géographie humaine

Par Prof. Max. Sorre. Tome 3: L'Habitat; conclusion générale. Pp. 500. (Paris: Armand Colin, 1952.) 1500 francs.

THIS is the third and last part—actually the fourth volume since the second part was issued in two volumes—of the great work which, for many years, has occupied Maximilien Sorre, professor of geography at the Sorbonne, vice-president of the International Geographical Union, and aptly described now as the *doyen* of French geographers.

He points out that it is the practice of naturalists to use the word habitat in a very broad sense, covering both a general environment such as a 'steppe habitat' and also the precise local conditions of an actual place. Normally, geographers tend to draw a distinction between 'habitat' in the broad sense and 'habitation' applied to an individual home. Sorre deliberately takes the widest possible meaning and hence leads from the general concept of the *œcumene*, or habitable part of the earth's surface, through the varied types of rural habitat, to the growth of towns and the great cities considered as environments wherein human beings pass their lives.

The field is vast in both space and time, and the bibliographies attached to each of the thirteen chapters show how widely the scattered literature has been studied, especially that of France, Germany, Britain, the United States and Italy. The bibliographies alone would render this work indispensable to the serious student of human geography, but the care with which the author has sought his material is matched by the care with which he has set out his findings. A laudable feature is the separation—in the case of the rural habitat into two separate chapters—of facts and theories. While much of the material on towns lies perhaps in the general field of sociology, an interesting chapter is devoted to large towns as a human *milieu* in which features of the local and micro-climates are examined. In another chapter the functions of a town are considered under three headings—social (listed as military, spiritual and political), exchange or commercial, and industrial. Among the difficult questions which inevitably arise are the definition of a town and the contrast with an overgrown village, the problem which has so much exercised town planners in recent years—the definition and delimitation of urban hinterland or *Umland*.

In the general conclusion to the whole work, which occupies the last forty-five pages of this volume, Sorre takes up briefly the vexed question of the natural region and its definition, and so leads to those areas of the earth's surface which have cradled the great civilizations of the past as well as of more recent times. He proceeds finally to the distribution of man on the habitable earth, noting the present-day development of power as a great localizing factor. The growing pressure of population on space he leaves, presumably, for his successors to worry about.

One would have liked more text-figures, since the thirty-two given, though appropriate enough, are all from familiar sources. So much scholarship deserves a better index: no authors are listed in the six pages devoted mainly to indexing places. On the other hand, a useful subject analysis to the four volumes is included. Proof-reading, especially of foreign authors' names and titles of books and papers, leaves something to be desired; but these are minor blemishes in a work of great value.

MOLECULAR ARCHITECTURE

Die Struktur des freien Moleküls

Allgemeine physikalische Methoden zur Bestimmung der Struktur von Molekulen und ihre wichtigsten Ergebnisse. Von Prof. H. A. Stuart. (Die Physik der Hochpolymeren, Band 1.) Pp. xxi+609. (Berlin, Göttingen und Heidelberg: Springer-Verlag, 1952.) 69 D. marks.

THIS is one of a series of four volumes by different authors designed to describe the physical architecture and properties of high polymers. But since polymers are built up out of smaller units, it is natural that the first volume should be concerned with the structure of a free molecule of not more than twenty or thirty atoms, and with the type of experiment which can be made to provide information about this structure.

Let it be said at once: this is a massive effort. The six hundred pages are literally packed with tables of numerical values, varying from interatomic distances and force constants for vibration to polarizability tensors and Kerr constants. Few people can boast such a wide experience in the physical behaviour of molecules as H. A. Stuart, now professor of physics at Hannover. It has been his intention to include between the two covers of this one volume every known approach to the study of molecular structure. The result of his efforts is something unlike any other account at present available. It will inevitably become a standard reference work for a good many years to come.

One is tempted to compare the present book with the well-known accounts by Prof. G. Herzberg, since these are the only comparable discussions of molecular structure on anything like the same scale. There is much less overlapping than one might have thought. This happy situation results from the different approaches of the two authors. Herzberg is interested in the internal structure of a molecule, and he is always asking: Why is this as it actually is? Stuart is chiefly concerned with discovering what the properties are, and with systematizing them, but without any desire to 'explain' them. If all reference to wave mechanics were removed, Herzberg's books would be mauled almost beyond acceptance; Stuart's book would scarcely be affected. For Schrödinger's name does not even appear in the author index, nor can wave mechanics be found in the subject index. The wave equation itself appears merely in a footnote, and then only in relation to the description of a highly simplified molecular system. Herzberg gives elaborate descriptions of molecular states; Stuart covers the electron classification in molecules in a couple of pages, and dismisses resonance in about the same space. But, for tables of dipole moments, the latest microwave results for bond-lengths, the polarizabilities of molecules and of bonds, depolarization factors, molecular association and intermolecular forces, the reader will look to Stuart and not be disappointed. The literature is exceedingly well covered, up to about 1950: when one realizes the extremely wide variety of fields under review, this is a quite remarkable achievement. Perhaps I was unlucky; but I found no less than five minor mistakes in the references in about half an hour's test.

As might be expected from such an author, there is a great deal of emphasis on the sizes of atoms and ions; and a great deal of information about the scattering of light by small, and large, molecules which is not easily found elsewhere. There are certain notable omissions, such as to the work of Ingold on the structure of benzene, and to the famous Jahn–Teller theorem on the stability of molecules with degenerate energy-levels. In one or two places, such as the ultra-violet absorption of polyenes and the free-electron model, the account seems to me rather inadequate; in one or two others, such as the old and larger value for the dissociation energy of F_2, it is a little out of date. But these are all relatively minor blemishes in a book which admirably serves its purpose of describing particularly those physical aspects of molecular structure which are relevant to the subsequent study of high polymers.

C. A. Coulson

BRITISH ASSOCIATION MEETING AT LIVERPOOL

SCIENCE FOR ITS OWN SAKE

By SIR EDWARD APPLETON, G.B.E., K.C.B., F.R.S.

PRESIDENTIAL ADDRESS

IN expressing my warm appreciation of the signal honour of being elected the Association's president, I would like to add how particularly agreeable the occasion is made for me by the fact that our meeting this year takes place in Liverpool. In my younger days all my journeys by sea began at Liverpool which thereby came to represent for me a gateway to adventure; and something of the old magic still remains.

Now, although our Association met four times in Liverpool before the University was founded, in the two succeeding Liverpool meetings the University has joined with the City in welcoming our members and organizing much of our week's activity. Our reception by 'town and gown' has been, on this present occasion, notably graceful and gracious, and I would like to tell both the Lord Mayor and the Vice-Chancellor how touched we have been by the cordial expression of their greetings and good wishes.

There is, I think, something very appropriate in our meeting here in Liverpool, a city whose interests and history have been so long and so closely bound up with the advancement of science. This happy conjunction has been remarked on by several of my predecessors and has been a fruitful source of inspiration to them. I have noticed, on looking through their addresses, how often their thoughts have turned towards the practical achievements of science and how often they have been able to cite their instances from Liverpool itself. It is interesting to note, too, how the city has served, through successive meetings, to point the direction which science was to take. The great developments that were noticed here by the Earl of Burlington at the first Liverpool meeting in 1837 were an indication of many things to come in other parts of the country before the turn of the century. Indeed, one might say that what was true of Liverpool at one British Association meeting was true of the rest of Britain at the next, and of most of the world by the one after that.

I confess that I stand somewhat in awe of my distinguished predecessors, who were inspired by this setting to range so widely over the fields of scientific progress in their own day. To succeed to an office which has been held here in Liverpool by such men as Rutherford and Lister and Huxley can be no easy task. It is not only the abilities of these men which now appear outstanding. What has particularly struck me, on reading their words, is the story of solid achievement each had to relate in speaking of recent scientific progress. "The heroic age of physical science" Rutherford appropriately calls the period that saw the first investigations of the radioactive elements, the discovery of X-rays and the development of wireless telegraphy. And, again, speaking of the period between the two Liverpool meetings of 1896 and 1923, he remarks "the epoch has been an age of experiment when the experimenter has been the pioneer in the attack on new problems. At the same time, it has also been an age of bold ideas in theory, as the Quantum Theory or the Theory of Relativity so well illustrate". Joseph Lister, at an earlier meeting, dwelt in his address on the same conjunction of experiment and theory, and how their application in the field of medicine had led, in his own time, to the ever-memorable discoveries of anæsthetics and antiseptic surgery. A similar sense of substantial achievement is conveyed in the words of T. H. Huxley. Devoting himself to a theoretical account of the genesis of bacteria, he nevertheless pauses in it to estimate that the practical applications of the theory, in the French silk-worm industry and wine trade alone, had—to quote his own words—"repaired the money losses caused by the frightful and calamitous war of this autumn"—he was speaking in 1870. In Huxley's remarks, indeed, I seem to detect a certain diffidence about entering the realm of pure theory at all, for, after apologizing to his audience for the dreariness of the theoretical approach to his subject, he continues: "Nevertheless you will have observed that before we had travelled very far upon our road, there appeared, on the right hand and on the left, fields laden with a harvest of golden grain, immediately convertible into those things which the most sordidly practical of men will admit to have value—namely, money and life."

What my predecessors had to tell was indeed a story of outstanding achievement. Yet what those great men had to say about the benefits of science can surely be equalled, if not surpassed, in our own day. It is true that nowadays we are more sharply aware of the debit, as well as the credit, side of our accounts with science, as my predecessor, Prof. A. V. Hill, reminded us last year. But no one could doubt that the material benefits of science are there and, indeed, are with us in our daily lives to an extent which even the nineteenth century could scarcely have expected.

Now the subject of my address, "Science for its own Sake", is already known to you. It was chosen to emphasize something that, at times, is in danger of being overlooked, namely, that science has interest as well as utility—that science is illuminating as well as fruitful. Having spent ten years of my own life in seeking to further the applications of science in the practical life of our country, I do not think I can be accused of under-estimating the vital importance of science as an instrument of material utility. I have long held the belief that the cost of scientific research is the price we must pay for our industrial progress. But we should be misleading the public, as well as ourselves, if we based our case for the general support of the pursuit of science on its utilitarian aspects alone. I know that we can claim that many discoveries in pure science, which in their time had no obviously practical import, have later proved to be the foundations of major improvements in our material civilization. But even that is an argument of profit and loss, and, to my mind, does not bring us entirely to the heart of the matter. I should like to go back, beyond the achievements, to the example of the scientist—be he amateur or professional—who is impelled solely by a passionate desire to explore and understand. That is what I mean by science for its own sake—when knowledge and insight are sufficient reward in themselves. Can the pursuit of a scientific vocation of this kind be a way of living worthily? Can it, in Dr. Johnson's phrase, help to advance us in the dignity of thinking beings? What values for us as individuals does it propound? As well as theoretical knowledge, as well as material benefit, is there some deeper, if more intangible, thing, even wisdom itself, to be found in our vocation?

I certainly make no claim to be able to provide the right, or the only, answers to such questions. At the most I simply hope to indicate to you where I think *some* of the value of a scientific vocation lies. After the extravagant claims that have sometimes been made on behalf of science—claims which have had the disagreeable consequence of putting the scientist on a pedestal—it is well that we should walk humbly. Yet, all the same, in a time of uncertainty of values and lowering of ideals, it is important that we should own to what we believe.

Now I begin by attempting to get the setting right, by pointing out that we scientists do not really inhabit the kind of universe which has sometimes been attributed to us. Science has so often been accused of having reduced the beauty and mystery of the universe to something cold and mechanical. When science enters the door, enchantment, it has been said, flies out of the window. You will remember the lines of the poet Keats:

> "There was an awful rainbow once in heaven:
> We know her woof, her texture; she is given
> In the dull catalogue of common things."

Now it is fairly easy to see how this attitude came about. The world of what is now called classical physics, as it was mapped out for us from the time of Newton onwards, had the advantage of appearing comfortably solid and tangibly final. Anyone, it seemed, who could understand why an apple falls from a tree could also understand the stars in their courses. In this light the universe might well seem to a poet to fail to come up to his expectations. We now know how misleading it was to regard this account of the matter as final. Perhaps the most striking fact about modern science, in its explorations ranging from the heart of the atom to the frontiers of the universe, is that, like poetry, like philosophy, it reveals depths and mysteries beyond—and, this is important, quite different from—the ordinary matter-of-fact world we are used to. Science has given back to the universe, one might say, that quality of inexhaustible richness and unexpectedness and wonder which at one time it seemed to have taken away from it. "The world will never starve for want of wonders," says G. K. Chesterton, "but only for want of wonder."

I hope to try to illustrate all this in a moment from the fields of cosmical research which have been my own interest for many years. But just now one general point I want to emphasize is that the scientific approach to things is a far more personal and imaginative activity than is sometimes realized. I am ready to admit that deliberate application to discovery can often take us some distance; also that important progress can result from the operation of a team of workers, as distinct from an individual, though this is mostly the case when the follow-up or consolidation of a basic discovery is in question. But the big jumps ahead are usually the adventures and intuitions of a single mind.

I need scarcely remind such an audience as this that scientific activities are twofold. We can make observations and experiments—that is to say, gather facts. We can also seek to understand how the facts fit together. We express any order we can discern among the welter of facts in the form of a hypothesis or a theory. A theory, by the way, is only a hypothesis that has become, so to speak, respectable. But even then there is nothing final about it. As J. J. Thomson once said, a theory is a policy rather than a creed.

Now, even in this question of making observations, the scientific process is one which requires the fullest and subtlest employment of all our faculties. It demands, for example, that we should not only see things, but should also notice them; and not only notice, but also perceive them. Many a vital discovery has been nothing else than recognizing the unexpected. To encounter Nature in this necessary state of awareness is inevitably to find all its forms and movements, from the infinitely small to the infinitely large, full of inexhaustible significance and relevance. But even in experimental work it is the primacy of an imaginative idea or intuition that often starts it all off. In simple words, I might say that the important thing in experimenting is to ask Nature the right question and in its more direct form. Only then is the answer clear and unmistakable. But so often one has failed to ask the right question and the terms of it have to be recast. In this complex process it is as if knowledge were playing a game of chess with the mind, and one has to be constantly on the alert with fresh tactics or even a changed strategy.

Many of our questions turn out to be wrong because they are unanswerable, but it is only by asking them at all that we eventually find we have asked the right one. One knows how oddly, how unreasonably I might almost say, the right question has often flashed into men's minds. It was recorded by the German physicist Helmholtz that his best ideas only came to him when he was walking slowly up a wooded hill—and significantly enough he was one of the founders of the principle of the conservation of energy! What I do know, from my own experience, is the fruitlessness of pondering over a scientific problem too long. The mind gets polarized and thought becomes captive to a groove. How often the best way of solving a scientific difficulty is to leave it alone! Also, speaking as a professional scientist who has only recently turned amateur, I would like to acknowledge the immeasurable debt which science owes to members of the latter category. My own subject of radio-physics has, on many occasions, been advanced by the observations of the gifted and enthusiastic amateur who was able to recognize the unexpected, even if his professional skill was insufficient to enable him to reveal its full meaning and implication.

Asking Nature the right question in the right way—or recognizing a theoretical pattern in a tangled skein of experimental data—often has the effect of introducing an element of beauty and elegance into the scientist's work. Do we not, on occasion, refer to a 'beautiful theory' and an 'elegant experiment'? It is perhaps a little difficult to say what precisely we mean by this. Not, I think, that the theory or the experiment is necessarily conclusive or irrefutable, or even particularly fertile in its consequences—that would be virtue of another kind. The quality I have in mind is that of inevitability—and yet, paradoxically enough, an inevitability which can cause surprise. A great experiment seems to us, somehow, something which could not have been done differently. Or, if it had, something essential would have been lost. We are surprised that someone thought of doing it that way, but we can see now that that way is really the only way to do it. Taking away something, or adding something, only detracts from it. In this respect a beautiful experiment can surely be classed with a great work of art.

Now I have spoken in general terms of the scientist's approach to Nature and of the kinds of mental quality and awareness that science requires in its followers. Also I have tried to suggest that the exercise of these skills has a value in itself which is ample justification of a scientific vocation. To go further might be claiming too much. Yet, I wonder. If we think of the great figures of science and, to be fair, restrict ourselves only to those we have known intimately, can we not go further and say that the scientific vocation, by its very nature, calls for personal qualities that deserve to be recognized and honoured? I might point, for example, to that tolerance and open-mindedness to new ideas which shines even from the printed page of Rutherford's address to this Association when he was president here thirty years ago—that freedom from prejudice, muddle, hypocrisy and darkening of counsel which characterized the man many of us were so privileged to know.

Yet, in less serious vein—a vein to which Rutherford was as much addicted as anyone else—ought we not, as scientists, to try to see ourselves as others see us? Joseph Addison once declared that there was this at least to be said for natural philosophy, that it occupied the attentions of men. who, if they had pursued public affairs and politics with equal zeal and vigour, would have set the whole country aflame. While Dr. Hartley in his "Observations on Man" declares that "Nothing can easily exceed the vainglory, self-conceit, arrogance, emulation, and envy that are to be found in eminent Professors of the Sciences, Mathematics, Natural Philosophy, and even Divinity itself. Temperance in these studies is, therefore, evidently required, both in order to check the rise of such ill passions, and to give room for the cultivation of other essential parts of our natures." Yet Adam Smith, in his "Theory of Moral Sentiments", finds far more to say in our favour. "Mathematicians and Natural Philosophers," he says, "from their independency upon the public opinion, have little temptation to form themselves into factions and cabals, either for the support of their own reputation, or for the depression of that of their rivals. They are almost always men of the most amiable simplicity of manners, who live in good harmony with one another, are the friends of one another's reputation, enter into no intrigue in order to secure the public applause, but are pleased when their works are approved of, without being either much vexed or very angry when they are neglected. It is not always the same case with poets, or with those who value themselves upon what is called fine writing." I only hope we scientists can see ourselves in that mirror.

For specific examples of what I have called the pursuit of science for its own sake there is, of course, no shortage of material on which to draw. I have, however, decided to tell you the story of only one field of development to-night—a long short story if you like—instead of a number of short stories in brief outline. My story has been selected because it bears on what men think about the world rather than what they do about it, for it concerns the nature of certain objects in outer space the nature of which has only been revealed in recent months. If I required a more homely title for my story it would be "Finding things out about places we can't visit".

From time immemorial men have examined the sky with their eyes, and found it to be populated with luminous bodies, the stars shining with their own, and the planets with borrowed, light. As time went on, telescopes were used to assist the naked eye, and in this way it was possible to see more feeble and more distant stars. Generally we may say that the bigger the telescope the more powerful it is in helping us to plumb further into the depths of space. The 200-inch telescope at Mount Palomar can detect stars so far away that it takes the light from them 1,000 million years of travel to reach us. In such cases the human eye is supplemented by the photographic plate which, through prolonged exposure, permits the photography of faint objects which can never be detected by the eye alone. In addition to the telescope the astronomer has also looked at stars with a spectroscope, by which the light from the stars is analysed into its constituent colours. In this way it has been possible to identify the kinds of atoms which exist in stars; since we know, from experiments carried out on the earth, how to recognize particular atoms by the particular colours—or wave-lengths—of the light they give out. We can call all observations of this kind optical astronomy since, in making them, we examine the optical light which comes from the stars.

Now it is of great interest to us here in Liverpool to-night to recall that it was Sir Oliver Lodge, one of the first professors in the University of Liverpool, who first thought of looking at the heavens with a "radio eye" instead of with an "optical eye". The year was 1900, in the earliest days of radio, and Sir Oliver tried to discover whether he could detect radio waves from our own particular star, the sun itself. The experiment failed because of the insensibility of the wireless receiver used—it was the day of the coherer. Yet it would be no misnomer to call Sir Oliver the first radio-astronomer, for the experiment was surely conceived on right lines and, with modern valve equipment, would have commanded success.

However, it fell to an American radio-engineer, the late J. G. Jansky, of the Bell Telephone Laboratories, to discover that radio waves, as well as light waves, could be received from the heavens. One interesting feature of this discovery was that Jansky found all this out when he was looking for something else. But with impressive scientific awareness he was ready to recognize the unexpected. Jansky was primarily studying the direction of arrival of atmospherics, but he noticed a persisting hiss in his ear-phones when his directional aerial was aligned to receive from a particular direction, which he later showed was the direction of the stars in the Milky Way. The year was 1931.

Jansky, appropriately enough, was the first person to speculate on the origin of this radio noise from outer space. He pointed out that the most obvious explanation was that the radio waves came from the stars themselves and that we get the radio noise in strength from the Milky Way because a great population of stars is concentrated there. But when he came to test his hypothesis by looking for radio waves from our nearest star, the sun, he obtained a discouraging result. For, even with the equipment available in his day, he found, like Sir Oliver Lodge, that no radio waves were detectable.

Now it is one of the remarkable features of the history of this subject that Jansky's researches incited only a few sporadic observations in the way of repetition. During the Second World War, however, radar operators, using their sensitive equipment operating on wave-lengths of 5–10 metres, so to speak re-discovered the phenomenon. But that was a period when one had to distinguish sharply between the scientific things that were only interesting as distinct from the things that were really useful. Quite a number of other matters of purely scientific interest arose in the same way, but all one could do was to note them and shelve them until the War was over.

I can well remember how these various topics cropped up, during the War, in the discussions of a panel of young scientific workers of which I had the good fortune to serve as chairman. This panel was really a small sub-committee, though it had a long name* and a distinguished parentage. It used to claim that, unlike most other war-time committees, its membership was confined to scientific workers and did not include officials. That I might have been classed in the latter category was generously overlooked. The task of the Ultra Short Wave Panel was to examine and interpret all the manifold vagaries of radar transmissions which were reported to it from operational experience and from *ad hoc* experiments. The Panel had to concern itself with many things, including, for example, the profound influence of the weather on radio wave travel in the lower atmosphere. The foundation of a new subject, that of radio-meteorology, was one result of its labours. That was a matter of practical moment. But the odd bits of information on radio-astronomy, though choice delicacies for a scientific appetite, had to be renounced. I have in mind here, in addition to the detection of radio noise from the Milky Way already mentioned, such subjects as the radar detection of meteors or 'shooting stars' and the detection—for the first time—of radio waves of violent intensity coming out of sunspot regions on the face of the sun.

Soon after the War, however, these matters became the objects of further inquiry, and it is of much interest to note that radar equipment, developed in the first instance for the detection of aircraft and ships, proved extremely useful for this purpose, requiring only minor adaptations. Dr. J. S. Hey and his colleagues, S. J. Parsons and J. W. Phillips, for example, made the first really detailed investigation of the amount of radio noise coming from different parts of the sky. For this purpose they converted a war-time radar receiver, which had been used in conjunction with anti-aircraft batteries, into a directional radio-telescope. Their work at once confirmed Jansky's original findings and showed that there was a close agreement between the intensity of the radio emission and the distribution of visible stars in the Milky Way.

Now I must digress from my main theme for a moment to remind you of a little of what is known about the distribution of stars in the universe as a whole. Our own solar system is really part of the Milky Way which is, itself, a colony or island of stars in space. This island colony has a structure like a magnifying glass, so that it is circular in shape but thicker at the centre than at the edges. You would not be far wrong if you thought of it as a Yorkshire tea-cake, the currants of which represent the stars. We inhabitants of one of the planets in the solar system do not occupy, however, a particularly privileged position in it, for we are situated nearer to the edge of the island colony than to its centre.

Space is, however, populated with far more stars than are to be found in our own Milky Way. But they are not distributed uniformly. They are grouped in island colonies exactly like our own. The astronomer calls these star colonies extragalactic nebulæ, and, with our big modern telescopes, it is possible to detect between 100 and 1,000 million of them. The average distance between any one of these star colonies or nebulæ and its nearest neighbour is about ten to a hundred times the size of either.

But I must resume my detective story about the radio noise from the Milky Way, for I think you will agree that it sounds much like a detective story as one clue after another is followed up. It was natural to assume at first that the radio noise coming from the sky represented the integrated radio effect of the stars in our own galaxy, since such stars are nearest to us. Our war-time experience concerning radio noise from the sun helped with the necessary calculations, for one could assume, as a first approximation, that all the stars would act like the sun. However, it turned out that there did not appear to be enough stars in the Milky Way to account for the high intensity of the radio noise. So then, as an alternative hypothesis, it was thought that possibly the noise came from the flying atoms and electrons which we know must populate the space between the stars. This was the inter-stellar matter theory. Unfortunately, here again, there were found to be difficulties. To account for the high intensity of galactic radio noise, when observed on the longer radio wave-lengths, required the ionized gas in inter-stellar space to be at a temperature of 100,000 degrees absolute, a value much too high to be reasonable. Also, we already knew that the inter-stellar material in question is concentrated in a narrow band near the galactic equator quite unlike the wide dispersal of both the stars in the Milky Way and the radio noise. So another theory had to be abandoned.

We had therefore arrived at this position, that the cosmic radio noise could not be accounted for as coming from the visible stars in the Milky Way or from the tenuous material existing in the spaces between the stars. However, this unpromising situation was soon relieved by an experimental discovery which, in its turn, led to others. Dr. J. S. Hey, observing the intensity of radiation from different parts of the sky, noticed that the strength of the radio noise from one particular direction—

---

* The Ultra Short Wave Panel of the R.D.F. Applications Committee of the Advisory Council for Scientific Research and Technical Development of the Ministry of Supply.

from a region in the constellation of Cygnus—occasionally showed rapid variations in a period of about a minute. At first it was thought that these fluctuations indicated variations in the emission from the source itself, but we now know that the variations are brought about by irregularities in the ionosphere, through which, of course, the radio waves must pass before they reach us on the surface of the earth. We can, in fact, look upon these variations as a kind of 'twinkling' introduced by irregularities in the atmosphere. But the most startling conclusion which could be drawn from these observations was that the source of this variable radio noise must be a very small one. In the case of visual light we all know that we can have a 'twinkling' star—because the star is a small source—but not a 'twinkling' moon.

Attempts were therefore immediately made to find out, by even more refined radio experiments, how big—or how small—in size this radio source in the direction of Cygnus actually was. There is no time to describe to you to-night the apparatus which was used, in Australia and in Cambridge, to test this matter, but I can assure you that both experiments qualify for my adjectives 'beautiful' and 'elegant'. Both sets of investigators announced the same result, that the source in Cygnus was too small to have its size assessed with the equipment used—that is, that it occupied less than a tenth of a degree in the sky. However, in the course of the same experiments, the position of this powerful radio source was fixed pretty accurately. Maps of known stars were eagerly consulted to see if the Cygnus radio star, as we may now call it, coincided with any special visual emitter. The result of this examination was most significant, for it was found quite impossible to identify the radio source with any particular star. Within the region which contained the radio star there were many faint visual stars to be found, but none of them seemed to exhibit any special peculiarities likely to associate them with the very powerful intensity of the radio emission.

Then, other parts of the sky were examined with the same apparatus and a further number of 'point' sources of radio waves were identified. One was found in the constellation of Cassiopeia, which was even more powerful than that in Cygnus. It also could be located with good accuracy. But, here again, there was no remarkable visible object apparent on the star map to connect it with.

It is important to pause here a moment to consider the effect of these observations on our outlook at the time. It was natural to ask a whole series of questions. Could it be that a radio star is always a dark star—and so a new type of object in the universe ? If so, could it be that there was a duplicate universe—only to be seen with a radio-telescope as distinct from a visual telescope ? As regards the overall phenomenon itself, could it be that the total emission of radio waves from the galaxy might be really the integrated effect of these dark stars, just as the diffuse band of light of the Milky Way arises from the unresolved radiation from distant optical stars ? You will see that the tendency of the time was still to think of the radio emitters as being neighbouring bodies and inhabitants of our own galaxy rather than of other, more distant, island colonies or nebulæ. However, a little reflexion will show that we must not rule out the possibility of radio nebulæ, as distinct from individual radio stars, even if we suppose that the greater part of our own radio noise comes from our own galaxy, the Milky Way. Any observer well outside the Milky Way should be able to detect the radio emission just as we, who are situated inside it, can do. Such an argument received strong experimental support when a group of radio-astronomers in Manchester noted a relatively faint, but quite detectable emission, from the Andromeda nebula, which is a neighbouring stellar island colony of our own. Further work, at Manchester and Cambridge, has revealed appreciable radio emission from other nebulæ not far from our own galaxy. It is clear that, in such cases, we are probably detecting their internally generated radio noise from the outside.

But the problem of the much more powerful sources remained. Where were they, why were they so powerful, and were they, basically, radio stars or radio nebulæ ? Again it was a case for more refined experiments which would enable their positions to be found with greater precision and give some notion of their sizes. I might mention here, in passing, that workers in Sydney, Australia, under the lead of J. G. Bolton, had already tentatively identified one radio star with the Crab nebula, a diffuse, expanding, cloud of gas which represents the remains of a stellar explosion, visible news of which reached the earth, according to Chinese records, on July 4, A.D. 1054. So this was another radio source, identifiable with a visible object, but it was of abnormal type, the ancient relic of a super-nova eruption.

The real attack on the identification of the two major radio sources, those in Cassiopeia and Cygnus, depended on the more accurate identification of their positions. In 1951 some new determinations were made by F. G. Smith at Cambridge and the results were communicated to the optical astronomers with an invitation to search afresh the parts of the sky in question. In the spring of 1952, a new and intensive optical search was therefore undertaken by Baade and Minkowski, at Mount Palomar, using the 200-inch Hale telescope and the 48-inch Schmidt telescope. As a result of this meticulous search, two entirely unknown objects were discovered in the universe. The Cassiopeia radio source was found to be associated with a diffuse cloud of luminous gas, situated within our own galaxy, and possessed of unique characteristics. The tenuous matter of which it is composed is concentrated in a number of fine filaments which are in the most violent motion. From a study of the colour of the light emitted by different parts of the same filament it is concluded that the velocities of such movement are of the order of several thousand kilometres per second. The origin of this gaseous cloud is unknown, for it seems impossible to regard it as yet another supernova explosion.

The source in Cygnus, which you will remember was the one which first gave the clue to the possibility of radio stars, was found to be an entirely different type of object. Here the source of the radio waves was identified with another exceptional object which is considered to be two island colonies—two extragalactic nebulæ—in collision. Moreover, the distance away of this compound group of stars is estimated as being such that it requires 100 million years for the light and the radio waves generated in it to travel to us here on the earth. It is rather a humbling thought that it is only during the past sixty years of that travel that human beings have managed to learn how to produce radio waves and receive them. Now when a collision of two nebulæ takes place it is considered that the stars of one island colony will pass freely between those of the other. On the other hand, the more extensive inter-stellar materials of the two island colonies will meet in collision, which will result in high excitation of the gaseous atoms of which this material is composed. One must suppose that, in both the radio source in Cassiopeia and the colliding nebulæ in Cygnus, the high gaseous velocities give rise to this intense radio emission, although the detailed mechanism by which it all comes about is not understood. These identifications were finally confirmed by observations in Manchester, Sydney and Cambridge using still more refined methods of finding the sizes of these radio sources. The results of all three radio-observatories were gratifyingly consistent and were published simultaneously last December. In all cases it was found that the radio sources examined were definitely much bigger than simple stars and therefore corresponded to the sizes of the objects observed optically.

The accurate location of these radio sources in the universe—we must now, I think, drop the term 'radio stars'—has therefore led to new discoveries of great astronomical interest. Two unknown objects of unique character have been identified in the heavens, as a result of clues from the radio side; and it is to be expected that future accurate measurements of the positions of those cosmic radio emitters will lead, in turn, to the discovery of other visual objects of uncommon types. I should explain that the discovery of these rare objects by direct visual search with large optical telescopes would require quite prohibitive effort. The radio-telescope has therefore shown itself to be an important adjunct to the world's greatest optical telescope. But, in addition, there is a further and far-reaching possibility. It is the astronomer's ideal to reach, with optical ranging, the hypothetical limit of the expanding universe, the distance where the extra-galactic nebulæ are receding from us with the velocity of light. So far he has reached very approximately half-way. But the fact that, already, the second most intense radio source can be detected without difficulty at a distance equal to one-tenth of the maximum distance plumbed by the 200-inch telescope suggests that it may, in time, be possible to detect sources at greater distances by radio than by optical means.

But, in any event, the more detailed radio mapping of the radio sources in the heavens must go on; for, as you will have gathered, we are still without an explicit solution of the original problem which started it all off, namely the rough overall correlation of the distribution of radio noise with the general structure of the Milky Way. Much progress in these matters can, I am sure, be expected from the operation of two large British radio-telescopes. Prof. A. C. B. Lovell's group is constructing a large steerable paraboloid of 250 feet diameter at Jodrell Bank, a station of the University of Manchester, which will be the largest single radio-telescope in the world and available for a great variety of investigations; while the large interferometric radio-telescope, recently completed at Cambridge, for work by M. Ryle and his associates, is already yielding entirely new results in the detailed mapping of radio sources.

The radio-astronomical story is therefore far from being fully told, but even already one can record achievements in these three centres of Cambridge, Sydney and Manchester—partly in competition and partly in collaboration—worthy to be ranked with the greatest feats in the art of experiment.

I have only a few words to add by way of postscript. I have tried to show how science, pursued for its own sake, can enlarge men's horizons and invest the world with deeper significance. As an exercise we can claim it to be one of the most complex and far-ranging of our mental experiences. But we must not forget that there are other values and other experiences. At the opposite pole from our scientific endeavour there are the ways of thought which do not change, whose concern is with what is *not* new, with the things that will not be superseded; and to-day we stand in need of these enduring and sustaining values of the spirit more than ever. We well know that, in the field of science, our work will in due course be probably out-dated and certainly surpassed. At any one moment we may have only a precarious hold on a temporary truth and our consciousness of this ever urges us to seek fresh truths and new understandings. I fear that, in doing so, we may lose sight of other aspects of life which have their values too. For, you know, there is a virtue in contentment, in being satisfied with what we already have, which we shall not learn from science. Our vocation, in other words, cannot be the whole of life, for it cannot satisfy all our needs. Nevertheless, I hope I have represented it fairly as no unimportant or unworthy part of it. For we scientists are specially fortunate in this, that our vocation can never be simply an occupation; it is, by its very nature, more than that—a dedication to an end. It often seems to me that what we lack in the world to-day is not so much the impulse to dedication as the opportunity for it. This, at least, the scientist need never lack; the opportunity is open to him everywhere "to strive, to seek, to find and not to yield". To those words of Tennyson's "Ulysses" I would add the words which Dante, long before, put into the mouth of the same Ulysses, when he encourages his crew to venture with him, beyond the furthest point of the known world:

> "O, brothers," he said, "who through a hundred thousand dangers have reached the West, deny not, to this brief vigil of your senses that remains, experience of the unpeopled world behind the sun. Consider your origin: you were not formed to live like brutes, but to follow virtue and knowledge."

To Ulysses and to Dante "experience of the unpeopled world behind the sun" meant, of course, the adventure of voyaging out into the Atlantic, where the sun set and the world came to an end. To-night, as I have tried to show, the scientist has commissioned the words to take on a different—and, indeed, a quite literal—meaning.

But we must still ask ourselves what it is that urges men to do these things, and our answer must surely be that it is the challenge of it all. Why should anyone want to climb Mount Everest? Simply, I suggest, because it is there—as a challenge of the unknown and the unaccomplished—a challenge to spirit and body, now so gloriously met by Hillary and Tensing. In its different setting, the pursuit of science also presents to the human mind an enduring challenge on an endless frontier, quite apart from the material enrichment of mankind to which it may incidentally give rise. "The work may be hard, the discipline severe," as Lord Rayleigh said on an occasion similar to this, nearly seventy years ago, "but the interest never fails and great is the privilege of achievement."

SUMMARIES OF ADDRESSES OF PRESIDENTS OF SECTIONS

HALF A CENTURY IN GEOPHYSICS

IN his presidential address to Section A (Mathematics and Physics), Sir Harold Jeffreys points out that the developments in geophysics in the twentieth century serve to illustrate some fundamental points in scientific method. The dispute on the age of the Earth had come to a head with Huxley's address of 1869. Helmholtz's contraction theory and Kelvin's theory of the cooling of the Earth had both led to estimates of the age of the order of 20 million years, but estimates from the rates of accumulation of sediments gave about 300 million years. Huxley emphasized uncertainties in the physical data, and incidentally cast doubts on the validity of the use of mathematics that, if accepted, would reduce science to mere cataloguing, since mathematics is the only method of testing whether a hypothesis explains the data. The discovery of radioactivity led to estimates of the ages of rocks, and it now appears that the age of the Earth is at least 2,000 million years and may be 3,000 million years. Radioactivity produces a delay in cooling that accounts for the discrepancy between these estimates and that of Kelvin. The estimate from the accumulation of sediments was wrong because the present rate of denudation is probably several times the average through geological time. It was suggested by Perrin and Eddington in 1920 that the maintenance of the Sun's radiation could be due to the conversion of hydrogen to helium, but a fully described mechanism had to wait for more knowledge of nuclear physics, and was not given until 1939, by Bethe and Gamow. The reconciliation of the results has been due mainly to increased co-operation between workers in different fields and to the development of the consequences of hypotheses far beyond the range of direct verification.

Poisson in 1829 had predicted that a solid should transmit both longitudinal and transverse elastic waves, and attempts were made to identify these with waves sent out by natural earthquakes. These were not successful until 1900, on account of low magnification and insufficient damping of the instruments used. R. D. Oldham achieved the identification, and it is from his work that modern seismology has developed. He also recognized in 1906, from the evidence of travel times, that the velocity of the longitudinal wave drops considerably about half-way to the centre of the Earth. Later work has shown that this corresponds to a central core, almost certainly liquid. The times of the elastic waves are now known to accuracies of order 1 sec. out of totals up to 25 min., and the velocities are known all the way to the centre with, on the whole, corresponding accuracies.

The study of gravity and certain astronomical observations give the Earth's mass and moment of inertia. The velocities of seismic waves yield a relation between pressure and density, and from this relation and the mass and moment of inertia the distribution of density can be found with some accuracy. The mean density of the core is about 10 gm./cm.^{3}, and would be in agreement with the hypothesis that the core is mainly liquid iron under compression. A sharp discontinuity of material is indicated by the fact that it gives strong reflexions. W. H. Ramsey has proposed an alternative hypothesis, that the core is of the same material as the rocky shell, but in a state of pressure degeneracy. This deserves detailed theoretical examination.

Earthquakes occur at various depths, up to about one-tenth of the Earth's radius. The mechanism of an earthquake is that gradually increasing shear stress leads to fracture when it reaches a certain amount. This is a normal process in an ordinary solid but not in any sort of fluid. Present knowledge of imperfections of elasticity does not suggest that it is ever valid to apply the mathematics of viscous flow, in which the rate of deformation is proportional to the shear stress, to materials with such rigidities as we find throughout the Earth's shell. These and other considerations are evidence against theories that require extensive convection in the shell. Thermal changes due to differences of cooling in an ordinary solid provide more hope of an explanation of rise and fall of the land surface and of mountain formation.

Terrestrial magnetism is coming into closer relation with the rest of geophysics than had been the case until recently. In particular, the electrical properties indicated should provide means of checking inferences about the thermal state, and Bullard and others are examining the hypothesis that slow changes of the magnetic field are due to electric currents in the liquid core.

The methods of geophysics are now being extensively applied for investigation of structure at small depths. The original motive was economic; but the methods are now being used for problems of pure geology and geophysics. The British Association, especially through its Seismological Committee and the Committee on the Thermal Conductivities of Rocks, has played a leading part in the increased co-operation between users of different techniques in this field.

ORGANIC CHEMISTRY SINCE 1837

PROF. G. R. CLEMO'S presidential address to Section B (Chemistry) commences with the reminder that, when the British Association first met in Liverpool in 1837, Liebig was among those who attended. Being imbued with a missionary zeal for organic chemistry, then developing on the Continent, Liebig made a strong plea for its advancement in Britain, and his advocacy created such an impression that he was invited to write a report on the application of organic chemistry to physiology and agriculture; largely as a result of the interest thus aroused, the Royal College of Chemistry was founded in 1845. Hofmann was appointed professor, and, inspired by Liebig's conception of organic chemistry, he made the institution a great centre of research.

Hofmann's inspiring prophecies so impressed a fifteen-year old disciple in 1853 that the first coal-tar dye, mauve, was discovered in 1856 by W. H. Perkin when attempting to prepare quinine, and in 1869 Perkin synthesized alizarin, thus fulfilling one of Hofmann's predictions. In spite of Perkin's remarkable success in developing the first industry to be based on research, it rapidly declined after his retirement in 1873 but prospered greatly in Germany. Following Hofmann's return to Berlin in 1865, nine years were to elapse before Roscoe established the first chair of organic chemistry in Britain at Owens College, Manchester. Under Roscoe's guidance, Manchester from 1857 became the centre for the training of chemists, and almost all the developing provincial centres filled their chemistry chairs with Owens men.

The earlier volumes of the *Journal of the Chemical Society* show that for many years from the middle of the past century much of the work done was inspired by the Hofmann school and laid stress on the importance of natural products. In the 1880's work began to appear from many other centres, but there was not a single school of organic chemistry in Britain to compare with many on the Continent. W. H. Perkin, jun., followed Schorlemmer in Manchester in 1892, and the development of organic chemistry since then in Britain owes a great debt to his school. However, it needed the First World War to shock the country into action on the industrial front; but if Liebig could return to-day he would surely exclaim that Britain "has surpassed all his notions".

Even so, we are scarcely at the beginning of understanding the synthetic methods of the cell whether for good or evil, and here the discovery of the isotopes of carbon and nitrogen especially should assist in the elucidation of what is going on behind Nature's curtain.

As one example, carbon-14 has been employed to gain a deeper insight into the reaction whereby the colourless tyrosine is transformed under oxidative conditions into the black melanin-type pigment such as is found in black hair and also in certain pathological conditions. H. S. Raper first established that tyrosine is converted into 5 : 6-dihydroxyindole carboxylic acid, which afterwards gives melanin. According to Raper's scheme, the carbon dioxide evolved in the reaction comes from the carboxylic group of tyrosine; but when this group is labelled with carbon-14, it is possible to prove that only about half the carbon dioxide evolved comes from this source. It is suggested that the catechol ring system undergoes fission, and this is supported by the fact that catechol itself under similar conditions evolves carbon dioxide.

Probably the greatest problem in the prevention of disease to-day concerns the origin of cancer. Recent statistics show that the incidence of cancer of the respiratory system is increasing in industrial areas, and this naturally focuses attention on the air we breathe. For a long time this has been contaminated by chimney smoke, but in recent years it has been aggravated by the black smoke emitted by buses and lorries which now fairly fill, and frequently foul, our highways. The contents of the filth collected from the air of a relatively clean city like Newcastle has been under examination, and some preliminary results are presented.

FOSSILS AND THE EVOLUTIONARY PROCESS

IN his presidential address to Section C (Geology) on "Fossils and the Evolutionary Process", Prof. T. Neville George points out that fossils, by placing organic change in a perspective of geological time, have illustrated evolutionary theory almost from the moment of publication of "The Origin of Species": first in the graded morphological series, then in the phylogenetic line, and now in the multi-variant lineage of successive populations. Recent palæontological theory has consequently come to show close parallels with evolutionary genetics: the one sees plexiform morphogenetic relationships, the other plexiform genetic relationships, between successional populations. Evolution in both appears less as a series of structural changes than as graded chronoclines in population-cluster. Correspondingly, adaptation among fossils is recognized objectively by continuing phyletic survival, and adaptive response by a systematic modal shift in successive populations; and despite the reputation of palæontologists for speculating along purposive and orthogenetic lines, the modern approach by-passes Lamarckian and finalist hypothesis.

A major problem in most groups of fossils is that of explaining divergent evolution—the orthodox branching phylogenetic tree. Speciation by the breaking-up of clines is not usually evident in fossil series, partly because of doubts about lineage-sequence and partly because of ignorance of the process of clinal disjunction among the marine groups to which the great majority of fossils belong. There are obvious difficulties in unravelling the 'adaptive radiation' of widely free-swimming creatures like cetaceans and ichthyosaurs. Neritic metazoans are more liable to local environmental selection, and disruption of species-range is indicated in fossil series by faunal diastems implying migration.

Systematization of the evolutionary process in fossils is difficult because phylogenesis is continuous, and speciation in geographical space as the product of evolutionary divergence is not to be equated with speciation in geological time as the product of successional change. There arises the notorious conflict between morphological and developmental species, the exemplary 'types' of the one being submerged as incidental individuals in the population-series of the other. The classificatory fragmentation of an evolutionary continuum must rest on a conventional basis, and must record not selected or abstracted units but lineage-segments. The resulting taxonomic model is not easily accommodated in a 'Linnæan' system but must manipulate integrated fields of transient forms.

The conventional taxonomic groups incorporating lineage-segments are never precisely clear-cut and distinct like genetical species recognized on the basis of reproductive isolation. Whether they are called sub-species or species or genera is therefore a matter of terms and not of things. Only when there is evidence of evolutionary divergence in lineage 'cross-sections', preserved on the momentary bedding-plane, may sympatric groups prove speciation and properly be called species. A conventional measure of successional change is usually dependent on the degree of overlapping variation-spread in successive populations; but it is defined only with difficulty, for the spread partly reflects the intensity of selection, which may show marked fluctuations from one 'generation' to the next. Moreover, ecophenotypic contrasts between fossil mussels and oysters have shown the difficulties that arise in attempting to distinguish between divergent and successional groups.

Finally, populations, although in current theory they are the convenient unit for analysis, exist only in the individuals composing them. A persisting problem is that of ontogenetic 'recapitulation', partly answered by interpreting evolution in many cases as having been brought about by mutant rate-genes.

But the apparent 'recapitulation' displayed in clonal astogeny, and the analogous complexities of shell-'recapitulation' in the Foraminifera, continue to be mysterious and await further co-operative studies by the palæontologist and geneticist.

THE MAINTENANCE AND SPREAD OF SEA-SHORE FAUNAS

PROF. J. E. SMITH, in his presidential address to Section D (Zoology), discusses the factors concerned in the maintenance and spread of sea-shore faunas.

Intertidal animals are protected by various anatomical, physiological and behavioural devices against the more obvious hazards of the shore, such as wave buffeting and the environmental changes which accompany the ebb and flow of the tide. These adaptations in themselves do not, however, explain the occurrence on the shore of some species and the absence of others, nor the variations in number and geographical range of different animals. The ability of animals to maintain their numbers through successive generations and to extend their range depends, in fact, not so much on the existence of adult adaptations and of conditions favourable to them as on the successful surmounting of hazards met with in early life. It is apparent, when attention is paid to the biography of individual species, that for each stage of the life-history there are requirements which are critical for population maintenance and dispersal. While these conditions are not the same for all species, there are certain elements of generality in the life-histories of intertidal animals and in the hazards that have to be faced which make possible a review of the principal conditions governing the maintenance and spread of littoral animals and a consideration of their bearing on the character of regional faunas.

The potentiality of a species for population replacement and dispersal is vested primarily in its fecundity and in successful ovulation. The two processes are independently controlled. Fecundity, largely an organismal property, is conditioned by the food supply, though little is known of the quantitative relationship in intertidal animals. Ovulation, on the other hand, is directly induced by measurable physical changes, particularly of temperature. This results in a severe limitation of the breeding season of animals living near the periphery of their temperature-range, leading, in all probability, to a reduction in fecundity.

The early stages of development of intertidal animals may be larval, embryonic, with or without brood care. The assumption is sometimes made that while larvæ serve for the dispersal of a species, embryonic development and brood care are more suited for the maintenance of more locally concentrated populations. The possession by many types of larvæ of adhesive mechanisms by which they resist displacement, the ability of many species to vary their mode of reproduction, and our lack of knowledge of the nature and extent of water movements on and near the shore point the need, however, for further investigation of the general conditions of dispersal of the juvenile stages.

In addition to the more obvious causes of mortality among the young brood, such as unsuitable physical conditions and the attacks of predators, the full effects of which have never been worked out in detail, it has recently been shown, in respect to Atlantic and English Channel water, that the chemical constitution of the different water masses has a direct effect on the course of development and the survival of larvæ. To what extent this may affect the character of shore faunas in different regions is not at present known.

A final critical hazard in the lives of intertidal animals occurs at the time of larval metamorphosis which, in many instances, is critically adjusted to the type of substratum available. Even if a suitable bottom is found, the young brood may be required to make extensive exploratory movements before they finally attain the distribution on the beach favoured by the adult population.

The nature and implication of these and other events, their bearing on the problem of the maintenance and spread of intertidal faunas, and their significance in the defining of the zoogeographical regions of the British littoral fauna are further discussed by Prof. Smith during the course of his address.

THE GEOGRAPHER AS HUMANIST

SOME people take the view that the only phenomena which can legitimately be regarded as geographical are those which show definite evidence on the earth's surface; but such an attitude, though it may suffice for the physical geographer, leads to a very narrow and ineffective conception of human geography, since it eliminates any real study of man himself. A view which is more satisfying mentally, and more fruitful in its results, is the one that admits a study of the various human groups in their regional diversities, and as influenced not only by their physical environments but also by the nature of their own adjustments to those environments. Moreover, this approach is in harmony with the dictum that the geographer's 'unit is the place or region', for do not human groups with their differing physical characteristics, their varied cultural or social backgrounds and their different economies, contribute something at least as vital to the distinctive quality of any place as do relief, rocks, soils, plants or air masses, despite the fact that the former are not necessarily shown on the ground ? This is the theme of the presidential address by Prof. R. H. Kinvig to Section E (Geography).

This attitude to human geography was a feature of the teaching of Prof. P. M. Roxby, who built up such a famous Department of Geography at Liverpool, where the first Honours School of Geography in Britain was initiated in 1917. Roxby, who had a very marked historical background, in addition to first-hand experience of several regions of the world, was able to develop very effectively various ideas he obtained from Herbertson, his tutor at Oxford. Although the latter's name is linked primarily with that of natural regions, he was deeply impressed with the need for systematic studies in the human sciences —anthropology, sociology and political institutions— on which he was engaged at the time of his death; and in a paper on "Regional Environment, Heredity and Consciousness", published posthumously, he showed clearly enough the direction of his thoughts.

The data of human geography can be most conveniently divided into four categories—racial (or biological), social, economic and political—which provide a useful working scheme, although there is much overlapping between these factors. They find their fullest fruition when brought together with the different aspects of physical geography and inter-related in a comprehensive treatment of some specific region, for example, tropical Africa, the Far East, or the local area. The evolutionary aspect of human geography constitutes historical geography, which has proved itself more and more to be an illuminating approach to the understanding of any period of history or prehistory, as well as being a prerequisite for any sound regional study.

This extension of the range of the geographer's contacts with the various social or human sciences is in keeping with developments which took place in the earlier part of this century in regard to the natural sciences. Objection was, indeed, raised in 1905 to the extension of the geographer's interest into the realm of geology and meteorology on the plea that the geographer did not "require to go beyond the purely orographical", and that he should not "intrude on geology or other sciences"; but it is quite clear that the subject would have wilted if this line had been adopted. So, too, it may be asserted that geography will only attain its full development when its growth is stimulated by both the human and the natural elements.

OPEN AND REPRESSED MONETARY INFLATION

PROF. F. W. PAISH states in his presidential address to Section F (Economics) that applied economics is more an art than a science. Its main problem consists not in discerning the relationships between given data but in choosing the data which can be regarded as significant for any given problem. Just as a dozen different artists may see a dozen different significant patterns in the same landscape, so each applied economist has to make his own personal simplification of the infinitely complex system of relationships which makes up the real world. The simplified models which he himself finds useful will therefore not suit everyone.

To Prof. Paish, inflation means, not a rise in prices, but a rise in money incomes without a corresponding rise in real incomes. Its cause is that people spend during a given period more money than they have previously received during the same period. There are two ways in which people can spend more than they have received in a given period: one is by spending money which they had in their possession at the beginning of the period; the other is by spending newly created money. Ordinary people cannot safely create money; but there are certain institutions, which can be called the banks, which do create money and lend it to persons, businesses, or the government. Such additional expenditures, whether out of previously idle balances or out of newly created money, cause inflation only when they are used for income payments; otherwise they merely raise asset prices and lower the rate of interest.

An inflation caused by the activation of idle balances may go to considerable lengths, but it cannot continue indefinitely if the quantity of money is limited. An inflation due to an increase in the quantity of money, on the other hand, can continue indefinitely. In the early stages of an inflation, money incomes are likely to rise more slowly than the quantity of money; but in its later stages, when further rises are foreseen, they rise increasingly faster, so that however much money is created the aggregate purchasing power of all the money in existence falls progressively towards zero, until eventually people refuse to accept it and its use is abandoned in favour of a new currency or even barter.

In a repressed inflation, such as existed in many countries during the Second World War, the government seeks to delay, by various devices, the rise in money incomes due to the increase in the quantity of money. Of these devices, the commonest is price-control, with or without rationing. In the early stages of price-control, while stocks are being depleted, idle money accumulates in the hands of retailers and other business men, who are unable to spend it on the replenishment of their stocks. Later, when stocks are exhausted, it accumulates in the hands of consumers who are unable to find anything worth while to spend it on. After the end of a war, therefore, there is more money in existence than is necessary to maintain the level of incomes. As controls, except perhaps in totalitarian countries, tend to break down in peace-time, the problem arises of how to prevent the excess idle balances from intensifying the inflation by creating additional incomes. In fact, except where part of the money in existence is cancelled, either by decree or by being redeemed out of the proceeds of a capital levy, the inflation has generally continued, at least until incomes have caught up with the quantity of money. If the quantity of money is allowed to increase further, the inflation may become an open one. One reason for the reluctance to limit the quantity of money and so ultimately to bring the inflation to an end is that the end of the inflation is likely to bring increased unemployment, and the world has not yet made up its mind whether it regards inflation as a greater evil than unemployment.

ENGINEERING IN THE NEXT 2,000 YEARS

THE presidential address to Section G (Engineering) by Lord Dudley Gordon looks forward to possible development in engineering during the next two thousand years, and commences by consideration of the available sources of fuel to provide power and minerals to supply raw materials out of which engineering equipment can be manufactured. Estimates as to the supply of the major fuels of coal and oil are discussed.

This leads to the consideration of the possible development of nuclear energy as a source of power and the future prospects for the supply of uranium. It is suggested that a long time may elapse before nuclear energy becomes the most important source for the production of power.

Another possible source of power is hydrogen, recoverable either from the air or from the sea, and the dangers of the release of large quantities of ordinary hydrogen are pointed out. Reference is made to Sir Charles Darwin's suggestion that there may be hopes of the successful use of heavy hydrogen as a fuel. Another source of heat which can be turned into power may be that existing in the inner part of the earth. In this case again there are obvious dangers which have to be avoided.

Sources of power which do not depend on the production of heat are water-power, which is already largely used and which will not be exhausted within any measurable period, and the energy derived from the use of ocean tides, which is again an inexhaustible supply. Wind is also an inexhaustible supply from which the production of power is already being undertaken. Further, there is a possibility of making use of heat from the sun's rays.

Some reference is made to the idea of controlling the force of gravity in such a way that it could be used for the production of power; but admittedly this is based on pure conjecture and is not supported by any knowledge existing to-day.

The increasing speed of air travel is discussed, and suggestions are made as to how this may have to be dealt with in the future.

With regard to supplies of materials for the development of engineering, it is suggested that iron and steel will continue to be the main source for several hundred years, and that further improvements may be looked for in the composition and structure of metals so that the same results can be achieved with a much smaller weight of material.

The science and practice of engineering will certainly be called upon to help in solving the problem of supplying sufficient food for the increasing population of the world, more particularly when it is realized that with the rising standard of living the demand for food will increase at a greater rate than the increase in the population. In this connexion the supplies from the sea will become a more and more important source.

The present generation of young engineers has not merely a great opportunity, but also a great responsibility, for developing methods which will make it possible for the progress of man to continue in future centuries.

ANALYSIS AND DESCRIPTION IN SOCIAL ANTHROPOLOGY

THE title of the presidential address by Prof. M. Fortes to Section H (Anthropology) is "Analysis and Description in Social Anthropology". He points out that the ethnographic monograph of to-day is as much a study of a problem as a record of the facts of observation. This is due to the influence of the functionalist theories and methods associated with the work of B. Malinowski and A. R. Radcliffe-Brown, but already foreshadowed in some of W. H. R. Rivers's ideas. Intensive study in one society at a time is thus used as a means of testing, amending and adding to the generalizations of social anthropology, and has in fact shown itself to be more profitable than the comparative method for these purposes.

Functionalist anthropology has proved to be so fruitful in theoretical contributions because it demands an analytical, as opposed to a descriptive, mode of investigation. It is true that even the simplest descriptive statements in ethnography imply the isolation of standard and recurrent features of custom, but it is at the higher levels of analysis that the significant theoretical problems emerge.

The essence of description in anthropology is that observations are grouped in accordance with their actual relationships in time and space. Thus a descriptive account of marriage starts with the heterosexual interests of children, then goes on to initiation ceremonies, courtship, wedding rites, and such legal formalities as the payment of bride price, ending, perhaps, with some discussion of divorce. The analytical method breaks up these empirical sequences and concomitances of custom and social relationships by reference to 'ideal isolates'. These isolates are theoretical constructions, and if they are to yield valid generalizations they must fit together in a system. A good example of an analytical isolate which satisfies these requirements is Malinowski's well-known concept of reciprocity. Again, Radcliffe-Brown's discussion of the functions of kinship institutions in distinguishing, ensuring and transmitting rights over things and persons develops analytical concepts. Analytically, we think of a custom or institution as if it were made up of a number of isolates, and of an isolate as if it were an element in divers customs and institutions.

Recent studies of marriage in African societies have shown how valuable an analytical approach is. A common view, long held, is that the essential feature of African marriage is the exchange of one woman for another, if not directly then through the mediation of the bride price. This seems to fit the descriptive observations. But analysis shows that this explanation is incorrect. What is really at issue is the transfer of rights which may be held conjointly or vested separately. The two sets of rights chiefly involved are those over a woman's reproductive capacity and those over her sexual and domestic services as wife; and these rights may be held by separate persons or groups.

This is strikingly brought out in societies that reckon descent, inheritance and succession in the matrilineal line. Studies already made in West Africa and Central Africa can be cited. But a better illustration is provided by unpublished field data on Ashanti marriage. From these data it is clear that a woman's lineage never alienates her reproductive powers. At the same time, a very high regard is paid to paternity, and the moral claims flowing from fatherhood are affirmed in marriage. In marriage, only rights over the sexual and domestic services of the wife are transferred to her husband, who thus acquires a claim to the paternity of the children, but not legal control over them. Cross-cousin marriage is one device for reconciling the divergent and often conflicting claims and rights of matrilineal kin, and kin through marriage and parenthood.

Analytical methods have been most successful in the study of social organization. Further advances will be made when they are extended to the study of the more complex aspects of culture, such as religion and art.

QUALITY AND QUANTITY OF PROTEIN FOR MAN AND LIVESTOCK

THE problem of quality and quantity of protein is ever present in our daily speculations about what we shall eat and wherewithal we shall be clothed. The scale of agricultural production to meet our needs has always been a matter of concern. Quality and quantity of protein cannot yet properly be separated. This forms the subject of the presidential address by Dr. D. P. Cuthbertson to Section I (Physiology).

Although the number of proteins in our foodstuffs is very large, they are constructed out of some twenty different units—the amino-acids—the position and preponderance of which in the molecule vary with each kind of protein and give to it its peculiar properties, some of which come to light in the processing and cooking of foods, and for man frequently provide an attractive texture.

The process of digestion of proteins ultimately provides the organism with these constituent amino-acids and possibly also simpler peptides. From these 'building-stones' the organism can create or renew the fabric of its tissues, its enzymes, hormones and other protein and non-protein–nitrogenous constituents. The evidence appears fairly conclusive that all the amino-acids that are components of a particular protein must be present simultaneously in a tissue before net synthesis will proceed smoothly. The individual proteins in the ration or diet tend to supplement each other in terms of the proper balance of nutritionally essential amino-acids. It is now known that, for man, several plant proteins and particularly mixtures of them are sometimes as efficient in supplying the essential amino-acids as some animal proteins, but that, in general, animal proteins, since they approximate more nearly to the needs of the animal and are free of cellulosic 'wrappings', are particularly well adapted to the needs of the growing child and for reproduction and convalescence. Further, associated with animal proteins are accessory factors such as the B-vitamins. We recognize that the demand for meat is not necessarily a requirement for protein. The extractives of meat stimulate appetite and provide these B-factors.

The requirements of the bird in respect to its feathering, growth of flesh and egg production are considerable and vary according to size, age and breed. From the qualitative point of view it seems that most of the amino-acids essential for growth of the chick are also essential for egg production in the adult bird. Success in compounding rations for non-ruminant livestock such as poultry and pigs is based on the optimal use of vegetable and, where necessary, animal products so as to provide the essential amino-acids in the right proportions and amounts, as well as vitamins of the B-group.

While in the ruminant micro-organisms break down protein in the paunch with liberation of ammonia, they also contribute abundantly to the supply of protein ultimately available for digestion in the abomasum and small intestine of the ruminant animal, rendering it less susceptible to critical deficiencies of individual amino-acids in its food proteins than other classes of stock and man. The degree of formation of ammonia in the rumen from the degradation of proteins may be an important factor in determining their usefulness to the animal. Processing may have effects on the value of a protein for ruminants quite different from those on the value for non-ruminants.

In the processing of foodstuffs for man, the sensitivity of amino-acids to destruction by heat must be kept continually to the forefront, and means sought to avoid their destruction; and in the case of cereals, improvers must be sought which do not damage their proteins.

Variations in the protein content of cereals through climate, fertilizer or genetic effects are probably of importance where the level of protein intake is critical, as in animal feeding.

The newer quantitative methods of estimating the amino-acids in protein based on the Moore and Stein chromatographic technique are of great value in elucidating the make-up of dietary proteins. The investigations in Belgium of Bigwood and his workers on cassava are noteworthy.

An inspection of consumption level in the United Kingdom shows that the percentage of the total calories in the diet represented by its protein moiety remains a very constant fraction irrespective of social class and level of energy expenditure. The rise in the consumption of animal protein which occurs wherever circumstances allow is particularly noteworthy when we consider that, from theoretical considerations, there is no proof that a proper mixture of plant proteins *per se* may not be as good for maintenance and even for growth and reproduction as proteins from animal sources, provided there is sufficient of it. But as we have observed, the demand for animal protein may be also a demand for its associated factors.

In animal husbandry, the farmer has learned to vary the proportions of protein and its quality in the feed according to the physiological need of the animal. In the Second World War the State assumed the role of husbandman also for its human population. In peace we like freedom, for we are less uniform than selected farm-stock.

PSYCHOLOGICAL PROBLEMS IN THE RECOGNITION OF EXCELLENCE

A COMMENT that might be made on contemporary psychology both by other scientists and by our colleagues in the humanities is that in its necessary concern with average and sub-average people it has given too little direct attention to those who are outstanding for excellence of some kind. This forms the topic of Prof. D. W. Harding's address to Section J (Psychology). It seems important to understand the conditions of excellent achievement, since general progress commonly occurs through advances made by unusual people and gradually followed up by the social group as a whole. The relation between outstanding people and the rest of us is part of the broader question of relations between people of different levels of ability or quality of mind. Waste of human resources occurs through the obstruction or neglect suffered not only by the very great but also by many people of more moderate excellence, including gifted children whose potentialities have not been discerned, and may excel those of their teachers and parents.

Two broad problems concern the psychologist: first, that of the mere perception of excellence, especially excellence surpassing one's own; secondly, that of the response to perceived excellence, whether it excites, for example, generous admiration or jealousy and attempted disparagement. A good relation between people of differing levels of ability depends on the attitude of the abler as well as that of the less able person. If the latter is to maintain his self-respect and psychological security he must feel that the other recognizes the value of his contribution, however small, to the common task; and recognizes his equality as a person, however subordinate his function may be. The ability to convey to subordinates one's recognition of their equality as persons is one mark of good leadership, and the basis of it deserves more attention from psychology. In some activities (for example, in amateur games and sports) the perception of excellence is aided by objective assessments of performance, and the response to it is so controlled by usage and convention that good relations are maintained between people of widely contrasting levels of ability. When less objective performances and more intangible qualities are in question, the difficulties of assessing oneself in comparison with others become formidable and various.

We know rather little at present, not only about the recognition of excellence in others but even about the psychological processes involved in making an advance ourselves and recognizing that our own present standards are higher than those we once accepted. Many of the unanswered psychological questions in this field are the concern of the social and experimental psychologist; others invite the aid of the psychopathologist, for example, the effect of the child's view of his parents and the effect of sibling jealousy on his later attitudes to greatness and superior achievement in others. Any direct psychological study of the conditions governing the achievements of distinguished people, whose minds may far excel those of the psychologists who undertake it, must raise special problems of technique which have up to the present received comparatively little attention.

EVOLUTION OF THE OVULE IN PTERIDOSPERMS

PROF. JOHN WALTON discusses the "Evolution of the Ovule in Pteridosperms" in his presidential address before Section K (Botany). The dominant groups of plants of the present day, the Angiosperms and the Gymnosperms, reproduce by means of seeds, and there is no doubt that the acquisition of this method of reproduction has been largely responsible for their dominance over other groups such as the ferns and their allies, which reproduce by means of spores. There is, however, some evidence to support the view that the seed habit has evolved from the spore habit, and it is likely that clues as to how this came about may be found among the fossil remains of plants of early geological periods.

In the fern type of reproduction the spores are liberated from the plant and produce on the ground small sexual plants (gametophytes), which are delicate structures dependent on moist conditions; their survival is often a matter of chance. For fertilization to occur, water must be present so that the male gametes can swim to the ovum in the female organ. This water is provided by rain or dew. Reproduction as well is therefore somewhat chancy. In seed plants the spore which produces the female gametophyte is retained in the ovule on the parent plant and once the pollen which contains the male gametophytes enters the micropyle in a gymnospermous seed or is deposited on the stigma of a flower the future development of the gametophytes and the process of fertilization are carried out within the protective integuments and are not dependent on external climatic conditions. The embryo is protected in its development and is provided in the seed with a food supply which on germination allows the seedling to build up a root and leaf system relatively quickly. Most seeds, moreover, can remain in a dormant condition during periods unfavourable for growth.

The earliest records we possess of plants which had seeds are from the Lower Carboniferous, which was about 250 million years ago. These extinct plants, to which the name Pteridosperms has been given, had the external appearance of ferns with large compound fronds, and the seeds were borne on these fronds. Their internal anatomy, however, differed considerably from that of ferns.

The seeds of the Pteridosperms have a complicated structure. The seed itself consisted of a nucellus, the part which corresponds to the spore case or sporangium of a fern, which contained as in modern seeds a single functional spore. The apex of the nucellus in the more primitive types of Pteridosperm seeds had a tubular structure, the salpynx, which captured the wind-blown pollen, which was then drawn down it into a special pollen chamber. The nucellus was partly enclosed in a sheath, the integument. In the primitive forms the apex of the nucellus was free so that the pollen reached it directly, while in the more advanced types the integument was almost completely closed over the nucellus, leaving a very narrow pore, the micropyle, to allow the pollen to reach the nucellus. The function of capturing the pollen was therefore assumed by the integument.

The evidence, too, suggests that the ancestors of these plants had fully exposed sporangia and that the integument was evolved by a concrescence of parts of the frond which formed an enclosure around the sporangium or nucellus, the whole structure constituting the ovule or seed. In the same manner, another investment of the seed was produced, the cupule or husk, in which the seed or in some instances several seeds were enclosed. Both the integument and the cupule contained vascular tissue.

There are two major groups of Pteridosperm seeds, the Lagenostomales and the Trigonocarpales. The former seem to be more primitive in construction while the latter are more evolved and are mainly restricted to the Upper Carboniferous. The Trigonocarpales do not have a cupule, but their structure suggests that this is because the integument had become much reduced and almost completely fused with the nucellus, and the cupule then assumed the function of a second integument of the seed. The seed of the Trigonocarpales type may thus be regarded as having a double integument like many Angiosperm seeds.

These early seeds were fully exposed on the fronds, in contrast to those of living Gymnosperms and Angiosperms, whose seeds are usually enclosed in cones or ovaries. It would seem that with increasing degree of enclosure seeds became simpler in structure, the nucellus reduced to undifferentiated parenchyma and the integuments losing their vascular tissue. In the Angiosperms, where the ovules are completely enclosed in an ovary and fertilization is effected by pollen tubes, the micropyle has in some apparently no function; and it is only in some of the more primitive Angiosperm orders that there is vascular tissue in the integuments.

GREEK OR CHEMISTRY OR BOTH

THE dichotomy which exists between the education of the humanist and that of the scientist is stressed by Dr. R. Birley in his presidential address to Section L (Education).

The great scientists of the Renaissance lived in the same cultural world as that of all other well-educated men of the time. They had the same educational background; the scientist had as an audience the whole of educated society. This unity has been lost, and in our culture there is a deep rift between the humanist and the scientist. The two have different educational backgrounds. The executive Civil Servant, who will almost certainly have had a humanist education, cannot understand the attitude of the scientist; the scientist has not been prepared by his education to accept the responsibilities which the power of science gives. Hence there is a feeling of helplessness in our society. Men who have social responsibilities feel helpless before a power which they cannot control or understand; men who control that power feel that they cannot concern themselves with the social responsibilities in which it involves them.

The existence of this dichotomy is widely recognized, and some attempts are being made to solve it at the universities by the introduction of general studies. Such attempts, however, do little more than paper over the cracks. The only way in which education can help to solve it is by ensuring that the two classes actually work together. This is impossible at the universities, and not much can be done in the sixth forms of the grammar schools, for in them children must spend most of their time on specialist work preparatory for the university. Moreover, by the time a boy or girl enters the sixth form he needs such specialist work for his full intellectual development.

The solution lies before this stage. The ablest children below the sixth form should work together at all subjects, except, perhaps, mathematics. They should study together the same humanist subjects, whether or not these include Greek, and take the same course in science. The abandonment of the 'half-specialization', now common below the sixth form, would inevitably entail some lowering of standards in the sixth form, and presumably in university entrance requirements, though by the time the educational process was finished it is doubtful whether the standards would be lower. All the ablest citizens in the country would then have had a common educational experience.

In the sixth form some periods should be set aside when boys and girls specializing in the various studies should again work together, at the humane subjects or science. This work would differ from ordinary specialist work, though the fact that all had learnt the grammar of the subjects should prevent it from being merely superficial. The scientist, when science was being studied, would do much to educate the specialist in a humane study, and, *mutatis mutandis*, the classic or historian would help the scientist.

It would not be easy to fit such a scheme within the framework of the national system of external examinations, which, just because they are devised to fit in with the requirements of the schools, make experiments by individual schools difficult. A far greater obstacle would lie in the most serious shortage of able science teachers in the grammar schools. This is now so acute that it is futile any longer to talk of the development of the scientific strength of the country or to plan institutes of technology or other similar institutions until it is remedied. Unless a solution is found to this problem, the universities will before long find that they have to teach elementary science.

APPLICATIONS OF 'ANIMAL PHYSIOLOGY' TO AGRICULTURE

THE theme of the presidential address by Dr. John Hammond to Section M (Agriculture) is that 'animal physiology' as a basal science for animal production has to co-ordinate the results of pure scientific research in anatomy, zoology, genetics, physiology, endocrinology and biochemistry, and to determine the interactions between these, so that control over animal production can be obtained. In doing this it is often found that large gaps in knowledge exist between the various pure sciences—for example, methods of control over the shape and composition of the animal—and these have to be filled in. While present-day medical and veterinary physiology can provide many techniques, they are too narrow in outlook and deal too much with critical short-time happenings in the body and too little with the chronic long-term results which are necessary in animal production. 'Animal physiology' is therefore supplementary to medical and veterinary physiology although it interlocks with them.

The rate and efficiency of the process of reproduction form the basis of economic animal production. At present the fertility of our farm animals is much below its potential level. The number of fertilized eggs which can now be obtained by injections of gonadotrophic hormones far exceeds the capability of the dam to mature them to birth, so that experiments are now in progress to find out whether eggs of good genetic worth may be transplanted to and incubated by dams of inferior genetic qualities. Such methods would also be useful for the cheap aerial transport of the larger domestic animals and for producing pure beef calves from dairy cows. Such things are now possible in the rabbit, and their application to cattle awaits development. The control of anterior pituitary gonadotrophin action by changes in the daylight–darkness ratio offers a method of regulating the breeding seasons in sheep and horses, which in the case of the former can now also be done by hormone injections. The application of the technique of artificial insemination to the mass improvement of dairy cattle, and to the production of beef cattle from dairy herds by the use of 'colour-marked' bulls, has already been extensively used in practice. The new deep-freeze method whereby bull semen can be kept fertile for at least a year offers possibilities for the pedigree breeder and for world distribution at cheap rates.

In milk production, studies of the mechanism of the 'let-down' of milk have resulted in better milking practices and machines. Sterile heifers can be brought into milk by the application of synthetic œstrogens, and good yields obtained in many cases. The effect of the plane of nutrition of the animal on the quantitative results obtained from hormone action, as shown by the 'steaming up' of dairy cows and the 'flushing' of sheep, is of great importance for economic production.

The development of early maturity and meat qualities in livestock depends on our being able to control growth and the relative proportions of the different parts of the body. Physiological and anatomical age can be advanced on chronological age by high-plane nutrition and retarded by low-plane nutrition. The maternal influences of uterine nutrition and lactation have a great influence on the development of early maturity in meat animals. The finding that the partition of incoming nutrients between the different tissues and parts of the body depends on the plane of nutrition is of importance not only for the economy of meat production, but also for methods of genetic selection.

The physiology of body-temperature regulation has important practical applications both for economic production and for survival under low air temperatures with pigs and under high air temperatures with cattle. The study of animal behaviour promises to create a science of the 'stockman's art'.

There is need for extension of the study of methods of control over animal functions if we are to develop an intensive animal production in Great Britain, for we must either do this or be content with a lower standard of living.

GATEWAYS OF SCIENCE

IN his presidential address to Section X (Assembly of Corresponding Societies), Dr. W. E. Swinton directs attention to the history and function of the new Assembly as descendant of the Conference of Delegates and contrasts them with those of other sections and the Association as a whole. He regards the meeting of the whole Association as the remnant of what was once tantamount to the annual meeting of the shareholders interested in national, if not nationalized, science—the remnant, because only a small part of the sectional business is nowadays within the comprehension of the general public, which is numerously represented in the annual meeting. In the circumstances, he feels that the Assembly has the duty of catering for many of these interested laymen and of reaching out beyond the annual meeting to the great masses of people who have a right to know about scientific plans and progress.

This is the more essential since it is becoming widely realized that the starting and maintenance of a scientific process or programme is only the beginning of a chain of events that might have great political and ethical results as well as intellectual by-products. Prof. A. V. Hill, at Belfast, directed attention to the dilemmas of science, to the need for orientation and re-orientation of its progress, and the members of the general public have a right to know, as beneficiaries or as victims, where they are likely to stand in the composite picture. There are also the many who follow science, as Sir Edward Appleton has shown, for its own sake.

The Assembly is the inheritor of a rich history of collaboration with the societies which, year after year, fight a battle, sometimes a losing one, for better public understanding of science, especially archæology and natural history. Many of these societies are old; it might be thought that the fight is no longer serious, that generally the recognition of so-called scientific truths is assured. Yet it is not so in many highways and byways; one does not have to work long in a museum or to give many broadcast talks to realize that the truths themselves are challenged, that the "Origin of Species" which sought to emphasize the rise of man is frequently interpreted as a sign of his fall. The biological study of man, it might be contended, has lowered his stature. Although the publication of Darwin's great work was an intellectual milestone, executions in England were still carried out in public for ten years after its first appearance; but there are many other better known social and medical facts which support the contention that the increase of biological knowledge has gone hand in hand with an increase in man's prestige.

To satisfy adequately the just demands of the general public calls for a rearrangement of the Assembly's outlook. There must be an increase in facilities for both the young and the not so young to have the best advice in scientific career fact-finding. Here the rich stores of experience in the Association should be tapped. There must also be increased facilities for the flow of authoritative information to the general public, individually or in groups of adult students.

The existing facilities in science for adults include: the libraries, museums, societies, the Workers' Educational Association, the B.B.C., and other bodies. It is clear from a conservative study of the figures available that there are thousands of persons almost habitually unable to attend the British Association meetings who are none the less well within the range that the Association desires to serve. In these circumstances a new form of membership—a corresponding membership—should be considered. This could be arranged so that aspirants to professional education and entry to the scientific services can have the advice they need. On the other hand, he outlines the kinds of services, reading lists and guidance in studies in and out of doors that could be given to adults and study groups. None of this need conflict with existing services but could be collated with and amplify them, and more immediately govern their trends.

Such a programme is important and will become increasingly so. It is important to consider the matter on a high level, and Dr. Swinton suggests a surveying committee to review and prescribe methods of co-operation between the British Association, Library Association, the Museums Association, the Unions of Scientific Societies, the Workers' Educational Association, the Further Education Section of the B.B.C. and representatives of the education authorities.

This would at least ensure the continuance of the great interest in the British Association's work and ideals which adults and the young, the regional and local education authorities, and many other responsible bodies have so abundantly demonstrated in Belfast and Liverpool. With it the gateways of science should be more freely opened.

OBITUARIES

Dr. M. H. Gordon, C.M.G., C.B.E., F.R.S.

WITH the death of Dr. M. H. Gordon, on July 26, aged eighty-one, British bacteriology has lost one of its outstanding figures, while the world mourns the passing of one who did good to all men. His work, much of which was that of a pioneer, has been deeply appreciated in his own country, and indeed throughout the world, by his professional brethren; but it is not primarily as an exponent of his profession that Gordon will be remembered by those who had the good fortune to be his friends—he will live in their memory because of his personal qualities, his geniality, his enthusiasm, his understanding and, in a very special way, for the kindness he showed to junior colleagues, many of whom owe to him a real debt of gratitude because of the encouragement given to them by him in their formative years. Widely read in many subjects far remote from his chosen speciality—literature, the fine arts and, above all, history—Gordon's companionship was both stimulating and satisfying. He inherited from his Scottish ancestors a liking for controversy, and an evening spent with him, enlivened by argument often acute but never bitter, was an unalloyed pleasure: he was one of those rare souls with whom one could agree to disagree and remain a firm friend.

Gordon's active life as bacteriologist and immunologist covered almost a half-century in which profound changes in outlook occurred and dramatic advances were made in the fields of preventive medicine and therapeutics. His early work was performed at a time when the technical armamentarium of bacteriologists was restricted; but he used the simplest procedures with ingenuity and with a consummate artistry which was delightful to see: indeed, he recalled what Max Gottlieb in "Martin Arrowsmith" regarded as the ideal research worker—one who fabricated his apparatus from a packet of tooth-picks.

Gordon's early investigations included the study of water-borne enteric fever, and in this, along with the late Surgeon-Colonel Reece, he carried out some of the earliest work on chlorination of water supplies. His study of the *Streptococcus* led him to believe that that micro-organism was the causal agent of scarlet fever and, although he failed to prove the validity of his views, his work made possible those later investigations upon which it is now accepted that that malady is due to infection with *Streptococci*. This work assisted greatly those who in later years defined clearly the mechanism of the pathology of scarlet fever and elaborated means for preventing that illness. As a bacteriologist, perhaps the most fruitful period of his life was during the First World War, when he was called upon to deal with cerebrospinal fever in the Armed Forces. The work which he performed, along with the team he so ably led, did much to elucidate the epidemiology, the bacteriological and the immunological problems of that malady which has proved a scourge to armies throughout history. The account of these investigations, embodied in a report to the Medical Research Council (Special Report Series No. 50; 1920), remains a classic.

In his later years Gordon devoted his attention to the study of virus diseases, notably the 'pock' infections, and he elaborated a procedure for the diagnosis of smallpox which, prior to the introduction of culture on the chorio-allantoic membrane of the developing chick, was the only accurate and delicate method whereby a diagnosis of modified smallpox or of smallpox minor could be made quickly. The Gordon flocculation test for the diagnosis of smallpox was used successfully to control more than one outbreak of smallpox minor, which presents problems of peculiar difficulty to the public health service. He played an important part in co-ordinating the work of those who contributed to the Rose research on lymphadenoma, and his interest in lymphadenoma was maintained throughout the remaining years of his life.

For many years Gordon was a member of the Advisory Committee on Pathology to the War Office, and for his services to his country he was rewarded by the conferment of the C.M.G. and C.B.E., while his contributions to the advance of knowledge earned for him the fellowship of the Royal Society and, perhaps what gave him most pleasure of all, an honorary LL.D. from the University of Edinburgh. A trait in his character which endeared him to all was that he accepted these honours as an appreciation not only of his own worth but as a recognition of the help he received, and which was given so willingly, by his collaborators. W. J. TULLOCH

Dr. Willoughby Gardner

DR. WILLOUGHBY GARDNER, who died on June 29 in his ninety-fourth year, was of Lancashire stock and the elder son of the late Henry Gardner, of Birkenhead, and of Caroline Huffam Gardner, *née* Willoughby. Educated at Rugby, he went into his father's business at Liverpool but retired as a comparatively young man for health reasons, and settled at Deganwy; there his numerous activities made him for many years a notable figure in the cultural life of Wales. He developed an area of land there as a unique building estate, under regulations which provided that the purchaser of each plot (already planted with trees and flowering shrubs) should build a house of character in keeping with the surroundings.

His early enthusiasm for fishing led him to the study of entomology; as far back as 1901 he published a list of the Hymenoptera Aculeata of Lancashire and Cheshire, and this group was his special interest. His collection of British Aculeate Hymenoptera, including material from North Wales, was presented by him about two years ago to the Zoology Department of the National Museum of Wales. He was a Fellow of the Linnean and the Royal Entomological Societies, and also of the Society of Antiquaries. His presidential address in 1928 to the Lancashire and Cheshire Entomological Society, dealing with the sixteenth-century entomologist Thomas Penny, shows a happy combination of his zoological and antiquarian interests, and was the result of much research.

A keen archæologist, Dr. Gardner was long a leading member of the Cambrian Archæological Association and of its various committees, and president in 1926. In his presidential address, published in *Archæologia Cambrensis* of that year, he summed up the results of his work on the significance and history of the great hill-forts of North Wales, many of which he had personally surveyed and planned, besides excavating those of Y Corddyn and Dinorben in Denbighshire. He was also a prime mover in organizing the excavation of the Roman sites of Segontium at Cærnarvon (by Sir Mortimer Wheeler) and of Kanovium at Cærhun on the River Conway (by Mr. Baillie-Reynolds). He was an original member of the Ancient Monuments Advisory Board for Wales, and of the Wales Advisory Committee of the National Trust and of the Board of Celtic Studies of the University of Wales. In recognition of his work in this sphere the University of Wales conferred on him in 1927 the honorary degree of doctor of science.

His interest in numismatics (he was a Fellow of both the British and the Royal Numismatic Societies) led to the formation, during nearly seventy years of his life, of a fine collection of Anglo-Saxon coins of the Chester Mint, which is now in the Grosvenor Museum at Chester.

One remembers Gardner as a man of wide interests, of great energy in pursuing them, and of "a nature sloping to the southern side".

COLIN MATHESON

WE regret to announce the following deaths:

Mr. W. A. Dillon-Weston, chief plant pathologist for the eastern province of the National Agricultural Advisory Service, on August 20, aged fifty-four.

Prof. C. Leonard Huskins, professor of botany in the University of Wisconsin, aged fifty-five.

Prof. L. Prandtl, For.Mem.R.S., of the University of Göttingen, aged seventy-eight.

Mr. T. Raymont, formerly principal of the Goldsmiths' College, University of London, on August 13, aged eighty-eight.

NEWS and VIEWS

Radar-Sonde Meteorological Station at Crawley

MULLARD, LTD., have given details of the *radar-sonde* system which they have developed in conjunction with the Telecommunications Research Establishment, Malvern, and which they are at present installing for the Meteorological Office in a specially built station near Crawley. The system is designed to measure winds up to heights of 100,000 ft. to an accuracy of 3 knots, and with the addition of some extra components it can also be used to measure pressure, temperature and humidity in the upper atmosphere. Pulses from the ground transmitter on a frequency of 152·5 Mc./s. are received by the airborne unit which is carried aloft by a free balloon. The pulses are re-transmitted to the ground on a frequency of 2,850 Mc./s. and are received by an automatic following aerial. The delay between transmitted and received pulses gives the range of the balloon; this is fed into a computor together with azimuth and elevation angles obtained from the inclination of the aerial system. Wind-speed and direction are computed and recorded from the rates of change of these parameters. When pressure, temperature and humidity are required in addition to the wind, a second pulse is transmitted by the airborne unit at a time interval after the first pulse depending on the value of the meteorological variable. A switch driven by an electric motor connects the pressure-, temperature- and humidity-sensitive elements to the *sonde* in turn. The system is capable of recording the meteorological information to an accuracy of one part in 1,000. This new equipment should provide weather information at greater heights and to a much higher degree of accuracy than obtained from the present *radio-sonde* and radar wind-finding system, particularly in conditions of high wind when the existing wind-finding equipment goes out of range of the ground station at comparatively low levels.

Australian National University : University House

THE Council of the Australian National University has appointed seven Fellows who, with a Master and an eighth Fellow yet to be appointed, will constitute the governing body of University House, the residential College which is nearing completion and will be opened for the coming academic year. Pending the appointment of a Master, Dr. W. E. H. Stanner, reader in comparative social institutions, will act as chairman and convenor. The Fellows already appointed are: Prof. P. A. P. Moran, professor of statistics (who will act as bursar); Prof. J. C. Eccles, professor of physiology; Prof. P. H. Partridge, professor of social philosophy; Prof. R. v. d. R. Woolley, professor of astronomy; Dr. Germaine Anne Joplin, Research Fellow in geophysics; Dr. S. Fazekas de St. Groth, senior Research Fellow in microbiology. University House, an imposing and beautifully appointed building, was designed by Prof. Brian B. Lewis, professor of architecture in the University of Melbourne. It will be the centre of the University's social and cultural life and will serve the ordinary collegiate purposes. It will be able to accommodate about 120 postgraduate students and members of the University staff.

Activities of International Scientific Unions

THE *Quarterly Bulletin* for May–June 1953 of the International Council of Scientific Unions reports briefly on the first meeting of the Executive Committee of the International Mathematical Union on February 13–14; it was arranged that the next International Congress of Mathematics will meet in Amsterdam during September 2–9, 1954, immediately following the Second General Assembly of the Union at The Hague, August 31–September 1. The preferred subjects for the symposia at the Congress are asymptotic expansions, non-associative, non-linear algebras, and stochastic processes. The Teaching Commission of the Union, which met in Geneva in October, selected for investigation the role of the contemporary mathematician and comparative studies of text-books in different countries, and has established close co-operation with the Section for the Teaching and Dissemination of Science of the Natural Sciences Division in the Secretariat of the United Nations Educational, Scientific and Cultural Organization. The Commission on Abstracting and Reviewing reported that no collaboration could be arranged between *Mathematical Reviews* in America and Julius Springer of Heidelberg, publishers of the *Mathematisches Zentralblatt*. An informal meeting of the interim Council of the International Union of Biochemistry recommended holding the first General Assembly of the Union early in 1955, before the next International Congress, scheduled for September 1955. At a meeting of the Executive Committee of the International Union of Geodesy and Geophysics in Paris in April, a special committee of the Union was appointed to co-operate with the International Council of Scientific Unions Committee for the International Geophysical Year. At a meeting in Madrid in April, the Executive Committee of the International Union of Pure and Applied Chemistry recommended that the Joint Commission on Physico-Chemical Constants and Data should become a Commission of the Union, but that the Joint Commission of Radioactivity should become a Commission of the International Union of Pure and Applied Physics.

Unesco Science Co-operation Office for Latin America : Report for 1952

A REPORT of activities during 1952 issued by the Science Co-operation Office for Latin America, Montevideo, of the United Nations Educational, Scientific and Cultural Organization (pp. 17; 1953) records the arranging of a symposium on new research techniques in physics, held in Rio de Janeiro and São Paulo, Brazil, during July 14–29, 1952, to which sixty original papers were contributed, and another on neurone and synapse, at Montevideo during October 6–12, 1952, to which thirty original papers were contributed. A meeting of experts on August 1–2 on the establishment of international and regional laboratories in Latin America recommended that the highest priority should be given to the creation of a network of international laboratories of marine biology, and that regional 'service-laboratories' for organic elementary analysis, conservation of microbiological type cultures, X-ray analysis and scientific films should be organized from certain laboratories now operating on a limited national scale. The creation of an Inter-American Institute for Cosmic Ray Research was also recommended. Three series of lectures by visiting men of science were arranged during the year, dealing with the theory of distributions (Prof. L. Schwartz), cardiac glucosides of rapid action (Prof. R. Mendez) and the clinical biochemistry of pregnanediol of urine (Prof. L. Corona). The Office now possesses a considerable collection of scientific films and is building up a film library from which scientific films are circulated in the Region. The Unesco travelling exhibition on physics and astronomy was shown by the Office in seven cities and aroused great interest. Microfilms amounting to 5,500 pages of text were supplied during the year to institutions and individual research workers, and seventy-five bibliographies were duplicated and distributed. The first catalogue of type cultures cultivated in Latin American laboratories was published in 1952 and included entries for thirteen hundred strains. Commencing in April 1952, the first four numbers of a bi-monthly *Bulletin* of the Centre were published, and the report includes details of the co-operation of the Office in technical assistance projects in Mexico, Bolivia and Montevideo.

Falkland Islands Dependencies Survey

THE Falkland Islands Dependencies Survey has begun a series of scientific reports, of which five have been published, the first being on "Organization and Methods" (pp. 12+3 plates; London: H.M.S.O., 1953; 4*s.* 6*d.* net) and the other four on various specialized topics. The Survey, which is under the direct control of the Governor of the Falkland Islands, has its scientific bureau at Queen Anne's Chambers, London, S.W.1, where all reports and photographs are deposited. The work is mainly a land organization and is concerned principally with survey; meteorology and hydrography will find other more suitable places of publication, and some of the biology will appear in "Discovery Reports" or in appropriate journals. The major task of the Survey is the topographical mapping of the Dependencies, and a series of 1 : 500,000 maps is now being revised; the first edition appeared during 1948–49, and larger-scale maps, 1 : 200,000 and 1 : 100,000, are also being produced for scientific work. Survey parties are attached to most of the bases, so that shorter or longer sledge-journeys will eventually cover the whole of Graham Land and adjacent islands and lands. After using various chartered ships, the Survey now has its own ship, the *John Biscoe*, a wooden ship of 870 tons with diesel-electric engines; she was formerly a net layer and has proved her capability in heavy pack ice.

Rugby School Natural History Society

A SCHOOLBOY at Rugby, J. B. Booker, has recently made a valuable series of observations into the breeding of swifts (*Apus apus apus*), which has been described in the Report of the School's Natural History Society (Report of the Rugby School Natural History Society for the Year 1952. Eighty-Sixth Issue. Pp. 29+1 plate. Rugby: George Over, Ltd., 1953). A similar study had been made in 1947 and Booker's investigations were designed to supplement this; in his case almost daily observations were made of six nests. The investigation was not started until after the eggs had hatched and no information was obtained about the earlier stages of breeding. Later it was seen that the daily increase in weight of maturing birds had a definite peak and also varied according to the weather. For example, most birds would lose weight after a day of bad weather when there would be little food available in the air. The weighing procedure was as follows: the young bird was carefully eased out of the nest and put in a paper bag of known weight; the bag was then hooked on to a spring-balance, and the weight of the bird found; the bird was then put on an improvised table and de-loused and returned to the nest. At first the young birds were frightened by the light from the torch and on being handled; most of them became used to the routine after about a week. Experiments were also carried out by introducing nestlings into nests other than their own. In one or two cases the introduced nestlings were ejected from the nest. Booker also tested the popular theory that swifts cannot 'take off' from the ground. Three parent birds were captured either on the nest or resting elsewhere, placed on the road and released. One bird hopped weakly and another hit its wings on the road for the first five or six beats. They then flew at an angle of about five degrees to the road for about fifteen yards, turned sharply to one side to gain speed, and commenced a zig-zag flight and rapidly gained in height. The Report also contains an article by R. C. Paul on double stars as well as the usual accounts of the proceedings of the different sections of Rugby School's Natural History Society.

Preservation of Museum Objects

THE second issue of *Conservation* (1, No. 2; June 1953), the journal of the recently founded International Institute for the Conservation of Museum Objects, includes several articles of interest and use to museum curators. Dr. A. A. Moss discusses the nature of niello and concludes that it is a black sulphide or mixture of sulphides. He also maintains that the technique of inlaying with niello changed about the eleventh century. Dr. H. J. Plenderleith and Mr. R. M. Organ deal with the decay and conservation of museum objects of tin. The first type of decay is a local chemical one in the form of disfiguring excrescences of oxide usually of a spotty nature and hard to the touch. The second type is the so-called 'tin pest' superficially rather similar in appearance, save that the spots are soft and powdery and tend to spread and in time to puncture the metal. These two types of decay arise from different causes, the first by chemical or electrochemical action in the ground, and the second, which is more serious, by protracted exposure to conditions of extreme cold, which causes a change of crystal structure. For the conservator, correct diagnosis is important, because, whereas oxidized metal is generally amenable to laboratory treatment, an object that has suffered the allotropic change to grey powder cannot be reconstituted. Other articles included in the journal concern the impregnation and lining of paintings on a hot table, and another on the joining of the loose members of panel paintings.

College of Commerce, Bangalore

ABOUT ten years ago, the University of Mysore established a College of Commerce at Bangalore, which now accommodates some eight hundred students and provides a degree course. A new building is under construction, to be known as the Ramnarayan Chellaram College of Commerce, and the foundation stone was laid by the Chief Minister of the Government of Mysore on August 1, 1952. The Ramnarayan Chellaram and Sons Charitable Trust has now issued an appeal for gifts of books to be presented to the College on the occasion of the opening of the new building; the appeal mentions especially biographies of industrialists and scientists and literature on the origin of industries and on the humanities. Communications should be sent to the Trust, Post Box 34, Bangalore 2, South India.

Conference in London on Applied Mass Spectrometry

A CONFERENCE on applied mass spectrometry, organized by the Mass Spectrometry Panel of the Hydrocarbon Research Group of the Institute of Petroleum, will be held during October 29–30 at the Institution of Electrical Engineers, Savoy Place, London, W.C.2. The main object of the conference is to bring together American, British and European workers in the field of applied mass spectrometry so as to discuss problems of current and future interest. The majority of papers are designed to interest those who use mass spectrometers in their daily work; but all the papers on the first day will be devoted to subjects in analytical chemistry where mass spectrometry has proved particularly valuable, and it is hoped that these papers will give rise to discussions of the relative merits of mass spectrometry and other methods. There will be eighteen papers in all, submitted by workers in Canada, France, Germany, Great Britain, Holland and the United States, and these will cover three fields as follow: quantitative analysis of gases, liquids and solids, including the continuous monitoring and control of product composition by mass spectrometry; applications to the study of molecular structure, free radicals, and electron-molecule collision processes; and recent developments in instrumentation and computing techniques. The fee for the conference is two guineas. Registration forms and further information can be obtained from W. J. Brown, c/o Metropolitan-Vickers Electrical Co., Ltd., Trafford Park, Manchester 17.

National Weed Control Conference

A NATIONAL Weed Control Conference will be held during November 3–5 at the St. George's and Norfolk Hotels, Cliftonville, Margate, under the presidency of Sir James Scott Watson, chief scientific and agricultural adviser to the Ministry of Agriculture and Fisheries. The Conference is being organized by a committee representing the Ministry of Agriculture and Fisheries, the Agricultural Research Council, the National Farmers' Union, the British Agricultural Contractors Association (representing spraying contractors) and the Association of British Insecticide Manufacturers (representing herbicide manufacturers). The aim of the Conference is to promote an interchange of views between those engaged in research and advisory work, on one hand, and farmers and others concerned with the subject, on the other, and special emphasis will be laid on chemical means of control in agricultural and horticultural crops. The formal papers will cover the following topics: the cost of weeds and potential value of herbicides (Dr. E. Holmes, Dr. F. R. Tubbs, Dr. J. Philp and Mr. M. V. Laurie); herbicides and grassland management (Dr. William Davies and Mr. G. Maxwell Davies); machinery and application problems (Dr. H. G. H. Kearns, Mr. Cameron Gifford and Dr. W. E. Ripper); weed seeds (Mr. F. R. Horne); weed control in farm ditches and on highways (Mr. C. V. Dadd and Mr. E. C. Boyce). In addition, reports will be presented by research workers from a number of stations on weed control in cereals, grassland, sugar beet, lucerne and forest nurseries and on wild oats, crop-desiccating agents and a new herbicide. The Conference will be residential, and the fee is £8 15*s*., including a copy of the proceedings. Provisional programmes and application forms may be obtained from the Conference Treasurer, Mr. W. A. Williams, Association of British Insecticide Manufacturers, 166 Piccadilly, London, W.1.

British Celanese Ltd. Research Studentships

BRITISH CELANESE LTD. announces the award of research studentships in chemistry, tenable for two years from October 1 at the institutions mentioned, as follow: Mr. V. A. Atkinson (Imperial College of Science and Technology, University of London), Mr. C. A. Baker (Merton College, University of Oxford), Mr. J. C. Maynard (University College, University of London) and Mr. W. Whyte Kerr (University of Glasgow).

Announcements

H.M. THE QUEEN has appointed Prof. T. M. Knox, professor of moral philosophy in the University of St. Andrews and chairman of the University Court, to be principal of the University of St. Andrews.

THE seventh Charles Chree Medal and Prize of the Physical Society will be presented to Prof. J. Bartels, of the University of Göttingen, in recognition of his valuable work in the field of geomagnetism, at a meeting of the Society to be held in the Science Museum, London, on October 23. Prof. Bartels will deliver a lecture on "Chree's Influence on Present-day Geophysics".

DR. A. GLUCKSMAN, of the Strangeways Research Laboratory, Cambridge, will deliver the third Douglas Lea Memorial Lecture at a meeting of the Hospital Physicists' Association at 8.15 p.m. on September 25 at the Hammersmith Hospital, Ducane Road, London, W.12. He will speak on "Radiosensitivity at Different Levels of Biological Complexity".

MR. J. SAVAGE, deputy head of the Physics Department of the British Iron and Steel Research Association, has been appointed head of the Department in succession to Mr. M. W. Thring, who is going to the University of Sheffield as professor of fuel technology (see *Nature*, May 9, p. 820). Mr. Savage has been closely associated with the Association's work on continuous casting since 1947. He was educated at the University of Nottingham, and for a time was in charge of spectrographic research at the Royal Aircraft Establishment, Farnborough.

Two useful booklets have been compiled by the Royal Institute of International Affairs (London and New York). One is a new revised edition of "World Production of Raw Materials" (Information Papers No. 18; pp. 104; 1953; 7*s*. 6*d*. net); in this publication, after some preliminary tables on raw materials, their geographical distribution, and trends in production and uses, there follow tables of statistics giving the output for the most important producing countries in pre- and post-war years, so far as these figures are available. The other booklet is entitled "Springs of Canadian Power", and is also a Chatham House Information Paper (pp. 59; 1953; 3*s*. 6*d*. net); it gives an objective picture of Canada's place in the industrial world, with a particularly useful section on the St. Lawrence seaway, and there are several sketch maps.

ERRATA. "Phagotrophy in *Oxyrrhis marina* Dujardin", by M. R. Droop (*Nature*, August 8, p. 250): paragraph 3, line 5, for "with particulate nutrients" read "without particulate nutrients".

"*Bact. coli* as a Food Supplement" (*Nature*, August 22, p. 351): the author's name should be "R. S. Roberts" and not "L. P. Roberts" as printed.

RECENT DEVELOPMENTS IN ULTRASONICS AND OPTICS

SUMMER PROVINCIAL MEETING OF THE PHYSICAL SOCIETY

THE summer provincial meeting of the Physical Society, under the chairmanship of the president of the Society, Prof. R. Whiddington, was held this year in the Physics Department of King's College (University of Durham), Newcastle upon Tyne, during July 13–14. The meeting was devoted mainly to the reading of papers in the fields of optics and ultrasonics, and on the morning of July 13 four papers on ultrasonic subjects were read.

Prof. A. van Itterbeek described two studies in the field of ultrasonics performed in the Low Temperature Laboratories of the University of Louvain: the use of measurements of the velocity of sound in a mixture of fluids to determine local concentrations and hence the coefficient of diffusion; and measurements of the velocity of sound in liquid helium I. In the latter case, previous measurements had all been made at one ultrasonic frequency, but, by using several sources, a dispersion of the velocity of sound in the neighbourhood of the λ-point has been substantiated.

The second paper, by Dr. L. E. Lawley, gave an account of some ultrasonic absorption measurements made in carbon dioxide contained in narrow tubes. The tubes were of the order of 1 mm. diameter, and the viscous drag at the walls was such as to produce an absorption of the same magnitude as the peak of the carbon dioxide relaxation absorption. The measurements showed that, over a considerable range of frequency/pressure on either side of the relaxation peak of carbon dioxide, the absorption was given by the sum of the Helmholtz–Kirchhoff tube absorption and the thermal relaxation absorption of the gas.

Mr. A. W. Pryor then presented absorption measurements in several solutions and dispersions. Measurements by means of a pulse method in the range 5–25 Mc./s. were correlated with measurements taken by means of a reverberation method by Mr. R. D. C. Reed in the range of 500 kc./s.–1 Mc./s. Relaxation curves for 1·5 per cent bentonite, 1 per cent gum tragacanth and several gum arabic solutions were presented. Viscous solutions of rubber in benzene and of 'Perspex' in pyridine showed an absorption less than that of the pure solvents. For solutions of cane sugar and glucose, for concentrations up to 70 per cent by weight and at temperatures 15–80° C., the ratio of the experimental to the classical absorption is little different from that for pure water.

Following this paper, Dr. R. Roscoe gave a theoretical discussion of Mr. Pryor's results for the absorption of sound in sugar solutions. It was suggested that a considerable part of the absorption in concentrated solutions results from a high loss of energy in the neighbourhood of the mean-points of adjacent molecules. Here the water molecules are extruded when the solution is compressed, and high stresses of a viscous character are consequently introduced. When this effect is taken into account, it is found by calculation that the ratio of actual to classical absorption should be much the same as for pure water, in agreement with Pryor's results. If similar considerations are applied to pure 'associated' liquids, regarded as mixtures of solid and liquid states, a value of 2·25 is obtained for the ratio of actual to classical absorption, while the observed values for alcohols and water range from 1·83 to 3·10.

The morning session of July 14 opened with a paper by Dr. G. W. Series, who described the work carried out at the Clarendon Laboratory, Oxford, on the Lamb shift in hydrogen-like spectra. It is now well established that the energy-levels of atomic hydrogen and ionized helium are not in the positions predicted by Dirac's theory. The shifts of the $2S$ and $3S$ levels in deuterium have been studied by measuring the components of $H\alpha$. The line width in the source was reduced by liquid hydrogen cooling, and two Fabry–Perot étalons in series resolved the structure. Details of this work have been published[1]. The structure of the He^+ line 4686 A. has now been studied in a similar manner. The doublet $3S_{1/2}$–$4P_{3/2}$, $3P_{1/2}$–$4D_{3/2}$ and nearly all the other components have been resolved, and it is concluded that the only levels which are appreciably displaced are $3S$ and $4S$. Provisional values are 0·139 cm.$^{-1}$ and 0·054 cm.$^{-1}$, respectively. Some weak components are affected by overlapping lines due to traces of molecular hydrogen, and work to overcome this difficulty is still in progress.

Dr. T. A. Littlefield described how ghosts had been found with the two reflecting échelons in use at King's College, Newcastle. The Foucault knife-edge test, used in conjunction with a mercury-198 lamp, showed clearly why ghosts were much more prominent in one than the other, which in use had proved acceptable. Since the knife-edge test was being applied to an interference fringe, a simple calculation determined the contour of the échelon surface. The possibility of figuring the échelon surface was considered; but preliminary attempts have so far been unsuccessful owing to the method of construction. The back surface of the échelon may also be used. The knife-edge test showed that this is as good as the acceptable échelon, and photographic tests of the figures have confirmed this.

Dr. E. E. Schneider began his paper on "Microwave Spectroscopy of Solids" by describing paramagnetic resonance experiments with zinc sulphide–manganese phosphors (down to a millionth part of manganese). Results on line widths and on the dependence of the resonance pattern on crystal structure were presented, particularly on a small scarcely resolved fine structure in cubic phosphors. Dr. Schneider then turned to results obtained with single crystals of sodium chloride containing manganese (0·01 per cent). Prior to heat treatment, only broad resonances are observed, indicating an aggregation of manganese ions. Moderate heating and quenching lead to a complex resonance pattern exhibiting both hyperfine structure and a strongly orientation-dependent fine structure which suggests that manganese ions liberated into the lattice are accompanied by cation vacancies. The paper was concluded by a brief account of microwave resonance experiments with coloured alkali halides.

The conversion of a Unicam *S.P.*500 photometer to an optical null-type of double-beam spectrophotometer was described by Mr. R. V. Hesketh. It was indicated that the accuracy of the instrument depends on the sensitivity of the null detector and the accuracy of the attenuator in the comparison beam. The null detector is a low-frequency oscillator of special design and forms a phase-sensitive detector of high sensitivity. Modulation of the light beams is produced by a mechanically resonant system requiring little power. The optical system employs a minimum of mirrors and is asymmetrical. The asymmetry is used to advantage in the design of the attenuator. This has a linear calibration throughout the transmission range. Errors due to the inhomogeneous intensity of the light beam are eliminated by the design. The performance of the instrument is such that a change of 0·005 in an optical density of 2 may be detected using a light intensity of 10^{8} quanta/sec. The scope of the instrument for work on activation of colour centres in alkali halides was indicated.

Dr. R. McWeeny gave a brief survey of "New Methods in the Wave Mechanics of Molecules", with emphasis on his recent revision of the valence bond theory (to be published). A molecular wave function may always be constructed from terms which, individually, represent electrons occupying a set of 'orbitals'. The molecular orbital approach employs one such term, the orbitals being non-localized; newer developments admit additional terms representing 'excited configurations'. But the valence bond theory employs localized, atomic orbitals and is essentially a many-term theory, a group of terms corresponding to each possible set of 'chemical bonds'. It is possible to work with such 'structures' only by assuming negligible overlap between different atomic orbitals; but this assumption is now found to be entirely untenable. The new theory employs orthogonalized atomic orbitals, the overlap assumption thereby being properly validated; but the resemblance between this 'valence bond theory' and its predecessor is found to be purely formal, the character, function and interpretation of the valence bond structures being quite new.

Drs. J. A. Abbott and H. C. Bolton presented an account of the theoretical polarizability of the helium atom. The unperturbed ground-state wave function was discussed in terms of functions arising from different configurations (using the recent work of Taylor and Parr), and the consequent correlation between the positions of the two electrons was shown. The perturbed wave function contains a term proportional to the electric field, and it was shown how this term can be constructed from functions of the right symmetry using the ground-state configurations and the perturbing potential. A variational method was employed to get the best values of the parameters in the perturbed wave-function. With the successive addition of configurations, there was a satisfactory convergence from the lower side on to the true value of polarizability. The method should be suitable for any wave function constructed from configurational functions.

INTERNATIONAL CONFERENCE OF PARAPSYCHOLOGICAL STUDIES

AN international Conference of Parapsychological Studies met in Utrecht during July 30–August 5 under the auspices of the University and with the financial support of the Parapsychology Foundation, Inc., of New York. Some sixty members of fourteen nationalities, comprising physicists, chemists, biologists, psychologists, philosophers, engineers and mathematicians took part in discussions of problems which arise in the investigation of those purported types of communication between individuals which are hitherto not explicable in terms of contemporary physics and biology.

After preliminary sessions, four working groups were established: the first dealing with quantitative experimental studies of various classes of alleged paranormal activity; the second with the interpretation of material gathered in psychiatric practice; the third with qualitative and spontaneous (that is, not experimentally controlled) phenomena; and the fourth with the psychological study of those persons who appear to display a large amount of paranormal sensitivity.

Attention was given to the establishment and maintenance of scientific standards, the development of appropriate experimental and quantitative methods, and the most profitable ways in which to combine and extend the concepts and methods of the various sciences in an attempt to understand more fully the relations between the living organism and the environment.

Marked interest was shown at the Conference in the problem of various methods of 'unorthodox' healing, and a medical committee was established and empowered to take preliminary steps towards the organization of an international research centre for the investigation and interpretation of outstanding cases.

At the conclusion of the Conference it was resolved to establish a secretariat and publication centre at the University of Utrecht, a series of committees being charged with arranging subsequent meetings of specialized groups in order to discuss more fully the experimental problems presented. The choice of Utrecht as the centre appears to be appropriate, since in 1951 the University founded an Institute for Parapsychology and in 1953 Dr. W. H. C. Tenhaeff was appointed as professor (*extra-ordinarius*) of parapsychology in the University.

THE MEDICAL RESEARCH COUNCIL

THE report of the Medical Research Council for the year 1951–52* is, like its two predecessors, selective, and it is emphasized that it omits many investigations being done by the Council's workers. The scope of the Council's work is nowadays so wide that this omission may be necessary; but some readers will regret that it is so and that we are given no more than the titles of so many interesting lines of research.

The report this year chooses for particular treatment the developments in clinical research, which has, until recently, been almost entirely observational, partly because of the difficulty of devising suitable experimental tests of generalizations derived from observation. Chemical and instrumental tests are, however, now available for use without risk to the patient, and statistical techniques have refined methods of planned observation and controlled clinical trials. Clinical investigation is therefore better able to study groups of sick persons and whole communities.

The Medical Research Council, when it was formed in 1913, gave its chief attention to clinical research, and its first clinical research unit, the Department of

---

* Committee of Privy Council for Medical Research. Report of the Medical Research Council for the Year 1951–1952. Pp. iv+241. (Cmd. 8876.) (London: H.M. Stationery Office, 1953.) 6s. 6d. net.

Clinical Research at University College Hospital Medical School, London, made important contributions to cardiovascular medicine. But it was Sir Thomas Lewis, a man in advance of his age, who trained a generation of research workers in the application of scientific method to clinical problems, and these men became available in the 1930's, when methods of clinical research were being elaborated. The Council itself established clinical research units and it is now spending more than £400,000 a year on investigations directly concerned with patients. When the National Health Service Acts gave virtually all facilities for clinical research to the Health Departments, close liaison and unanimous agreement were established between these Departments and the Medical Research Council. It is now proposed that there should be a central organization for the promotion of clinical research, which should be a part of the Medical Research Council, that provision should be made for decentralized research with the greatest possible freedom from supervision and that careers in clinical research should be equated with careers in the National Health Service.

The main interest of scientific readers of this report will no doubt be in the section of it entitled "Some Aspects of Medical Research", which reviews the results obtained by the Council's workers in certain fields. Dr. A. J. P. Martin, of the Division of Physical Chemistry, National Institute for Medical Research, and Dr. R. L. M. Synge, of the Division of Biochemistry, Rowett Institute, Aberdeen, have been jointly awarded the Nobel Prize for chemistry for 1952 for their work on partition chromatography. This section of the report gives an interesting account of the development of chromatography since 1906. Mental deficiency is discussed and the impressive work of the Council's Research Unit on Occupational Psychiatry is described. The Council's work on the causes of maternal and child mortality and on the social aspects of this important subject has as its ideal a pregnant mother who feels well and has a spontaneous and easy labour and gives birth to a lusty child which she is able to feed successfully, and the results obtained have done more for the nation than many people realize. The importance of the glands which produce internal secretions has long been recognized, and the Council's workers at Cambridge who have been studying the close relationships between the central nervous system and the posterior pituitary gland during lactation have shown that the action of sucking excites a nervous reflex in the mother which causes secretion by the posterior pituitary gland and the liberation of a hormone which acts on the mammary glands and causes the 'let down' or ejection of milk. The oxytocic hormone is the most powerful in this respect, and this hormone also stimulates the contraction of the uterine muscle. This work thus provides an explanation of the age-old observation that suckling the young helps the contraction of the uterus after labour. The Cambridge workers are also studying the anterior pituitary gland and the control of the secretion of corticotrophin by this gland.

The section of the report mentioned above also considers work on bacterial food poisoning, the development by bacteria of resistance to drugs, the etiology, mechanism and diagnosis of hæmophilia, hearing-aids and diseases of the ear, the thyroid gland and the uses of radioactive iodine in medicine, the epidemiology, pathology and treatment of poliomyelitis, the physiology of the red blood cells, each of which lives for an average period of 120 days, the synthesis of porphyrins and hæmoglobin in the body and the formation of bile pigment.

The rest of the report provides details of the various units of the Medical Research Council, the names of their staffs and bibliographies of papers published by them and by members of that valuable organization, the Public Health Laboratory Service, and by workers in the Institute of Cancer Research.

All those who work for the Council, whether they are members of the Council itself or are research workers, or perform those unpublicized but highly skilled tasks upon which all modern scientific research depends, deserve the gratitude of the public for whose health and welfare all this devoted work is so patiently and efficiently done. G. LAPAGE

SCIENCE AND FREEDOM

THE International Congress of Science and Freedom held a meeting in Hamburg during July 23–26, which was attended by more than one hundred delegates from nineteen countries, including fourteen from the United Kingdom. The purpose of the meeting was to discuss the danger to cultural freedom which has arisen in totalitarian countries, especially those behind the Iron Curtain. The delegates, among whom were four Nobel laureates, included leading representatives of other branches of learning in addition to science.

The opening session in the Rathaus was addressed by Dr. Max Brauer, mayor of Hamburg, Prof. Bruno Snell, rector of the University, Prof. Denis de Rougemont (Geneva), president of the executive committee of the Congress for Cultural Freedom, Prof. James Franck (Chicago), Prof. J. Pieper (Münster) and Prof. Max Hartmann (Tübingen). The twenty communications which were considered during the meeting included papers by Prof. Michael Polanyi (Manchester) on pure and applied science and their appropriate forms of organization; Dr. J. R. Baker (Oxford) on scientific authority and the system of scientific publications; Prof. S. K. Allison (Chicago) on requirements of security and academic freedom; Prof. T. Dobzhansky (New York) on biology in the U.S.S.R.; Prof. G. v. Rauch (Marburg) and Prof. V. Gitermann (Zurich) on history in the U.S.S.R.; and five papers devoted to "Neutrality or Profession of Faith" and "Moral Responsibility and Science". The various communications aroused much discussion, and it was often difficult for the respective chairmen to keep the speakers to the prescribed time limits.

It was generally agreed that totalitarianism to-day constitutes the greatest and most potent threat to cultural freedom, and the infiltration of Communist ideas into the circles of academic teachers and students has often given rise to a general distrust of the universities as seed-beds of intellectual insubordination. This has led frequently to the demand that universities should recognize without question existing economic and social systems in their respective countries.

The independent position of universities has been further impaired by the fact that they have become increasingly dependent on government grants. These tend to foster those fields of science in which some practical or economic advantage is to be expected. In addition, the Second World War has resulted in the suppression or corruption of many of the older universities of Europe, with their deeply rooted traditions of academic freedom. This has very seriously diminished the sense of cultural obligation among the public to support the progress of pure science, and it has become rare nowadays to hear the head of a university appealing for funds for the advancement of knowledge as an end in itself.

At the final meeting it was agreed to issue the following message: "At the conclusion of this International Conference in Hamburg on Science and Freedom in which more than 100 scientists and scholars from 19 countries have discussed the theoretical and practical problems of scientific research today, we should like to convey our fraternal greetings to our fellow-scientists separated from us by political power. We are convinced that these, our unhappy colleagues, have never ceased to feel a profound loyalty to those ideals of free inquiry without which science itself would never have arisen. We look forward to the day when they can sit down with us as free men at such a conference as this, to discuss our common problems in a spirit of sincerity and objectivity that they must surely cherish under the most difficult circumstances".

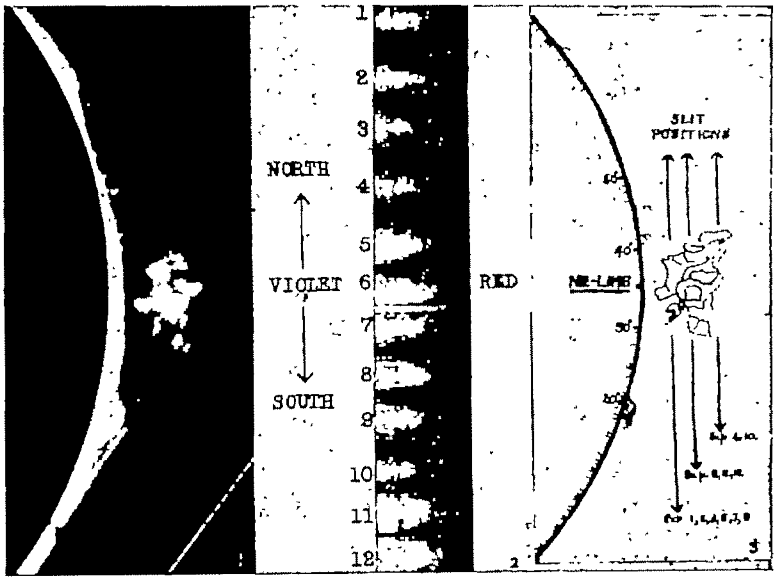
EDWARD HINDLE

ERUPTIVE PROMINENCE OF FEBRUARY 26, 1953, AND ASSOCIATED RADIO NOISE-BURST

AFTER a period of rather pronounced inactivity characteristic of the present minimum phase of the sunspot cycle, an interesting type of activity occurred on February 26. On the previous day a rather insignificant-looking prominence had been observed on the north-east limb at a mean latitude of 40°. On the morning of February 26 visual observations with the spectrohelioscope and photographs obtained with the spectroheliographs between 0200 hr. and 0400 hr. U.T. showed that the prominence had grown somewhat in height and had also extended southwards to about lat. 30°. There was, however, nothing unusual in this, for this increase in size could easily be regarded as the coming into view of parts of the prominence previously behind the limb. There was no visible sunspot in the neighbourhood of the prominence; but the spectroheliograms taken on February 28 and March 1 showed a *plage faculaire* around lat. 22°. Observations during the early hours (0200–0400 hr.) of February 26 showed that the prominence was of the quiescent type.

Between 0400 hr. and 0430 hr. there was no certain sign that the prominence was working up for an eruption, although some slight agitations were noticeable. However, a control observation with the spectrohelioscope at 0500 hr. revealed a very different picture: the height of the prominence had grown to 150″, or about double its previous height, and large Doppler displacements were also apparent. At the base the Doppler shifts measured were 1·2 A. towards red (about 55 km./sec.), while the top portions of the prominence were showing displacements of 1·4 A. towards the violet (about 65 km./sec.). Until 0507 hr. the prominence was still adhering to the sun's surface; but from 0510 hr. it broke off from the limb and the next 30 min. saw the most active phase of the eruption. Some parts of the prominence reached a height of 260″, and the maximum Doppler displacement observed in some parts was of the order of 6 A. to red (270 km./sec.). The eruption reached its peak by 0545 hr., after which the prominence—a compact mass until then—began to disintegrate. Two well-developed streamers could be seen descending from the eruptive mass to the sun's surface and exhibiting Doppler shifts of 3–4 A. to violet (135–180 km./sec.), where they met the limb. The ejected prominence matter was apparently being forced back to the sun's surface at lat. 22° through these streamers. By 0700 hr. it became difficult to identify clearly the prominence and its streamers, and in another half-hour the whole phenomenon had subsided leaving no trace of the prominence. From the above description of the course of events this eruptive prominence would probably be classed best as a 'surge' of Class IIId in Pettit's classification, although it was not visibly associated with a sunspot group.

Luckily the prominence was so located that the spectrohelioscope slits were almost exactly tangential to the part of the limb where the prominence was. As our spectrohelioscope has no arrangement for rotating the image, this circumstance made it possible to take spectrograms at definite heights in the prominence with the help of the camera[1] attached to the side of the spectrohelioscope. Altogether twenty spectrograms were secured in the H_α region with exposure times of 2–4 sec. each. The first twelve of these were obtained between 0535 hr. and 0545 hr. while the prominence was moving away from the limb as a fairly compact mass (Fig. 1). The other eight spectra were photographed between 0620 and 0625 hr. with the first slit of the spectrohelioscope cutting across the two streamers; although these spectra also give some interesting information, we shall not consider them in the present communication. The first twelve exposures (Fig. 2) reveal interesting details concerning the



Figs. 1–3

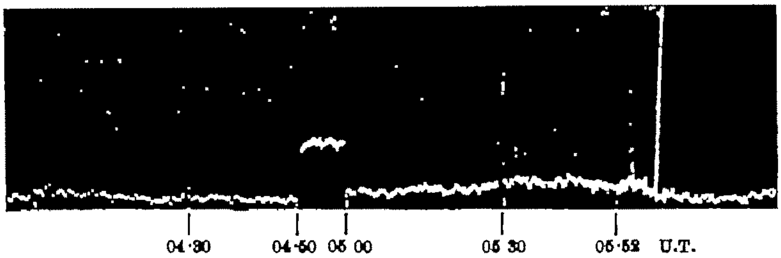


Fig. 4

motion and structure of the prominence before disintegration with which we are here concerned. Six exposures (1, 2, 3, 5, 7 and 8) were made on the parts of the prominence nearest to the limb (height above limb 55,000 km.), three exposures (9, 11 and 12) at about the middle (height above limb 85,000 km.) and two exposures (4 and 10) on the topmost parts of the prominence (height above limb 140,000 km.), but exposure No. 6 had just missed the prominence (Fig. 3). In all the eleven serviceable spectra, the strong H_α emission line due to the prominence appears practically as a straight line. Spectra 4 and 10 made on the upper peripheral parts show the bright H_α line shifted towards the violet by about 1 A. parallel to the H_α absorption line of the background; the topmost parts of the prominence, therefore, had a 45-km./sec. velocity of approach in the line of sight. The rest of the spectra, which correspond to the lowest and the middle parts of the prominence, show the bright line intersecting the absorption line, its ends displaced equally by about 1 A. on either side of the absorption line and therefore indicating a rotational velocity of about 45 km./sec. around an axis perpendicular to the line of sight. The sense of the rotation is clockwise as seen from above the prominence.

This prominence therefore had the primary characteristic, namely, rotatory or helical motion, of the tornado type of solar prominence, even though it had neither the columnar nor the crossed lattice-work appearance which is supposed to distinguish the tornado type from other types. However, this particular eruptive prominence seems to have had the properties both of a surge and of a tornado. On one or two occasions in the past we have also noticed a spiral motion around the length of long stable hydrogen absorption markings. It is, of course, not easy to detect observationally such spiral motion in prominences and dark markings, but it probably occurs much more commonly than is believed to be the case. It seems possible to form a purely dynamical picture of the general mechanism of prominence formation in which spiral motion plays a significant part[2].

Another phenomenon to which we would like particularly to direct attention is the occurrence of solar noise bursts in association with this eruptive prominence. On February 26 the radio telescope of this observatory, which works on 100 Mc./s., recorded three bursts of solar noise. The first one occurred between 0450 hr. and 0500 hr., the second, which was stronger, was recorded between 0528 hr. and 0534 hr., and the third, which was the most intense, occurred some time after 0552 hr. (Fig. 4). Unfortunately the recording drum stopped three or four times while the third burst was in progress, and therefore we are not absolutely certain of the times of beginning and ending of this burst. During the first burst the noise intensity suddenly increased at 0450 hr., remained above normal for about ten minutes and then dropped to normal at 0500 hr. without showing the usual series of isolated peaks at short intervals. The second burst showed three separate peaks (although these peaks are unmistakable on the original record, they had to be made more prominent by slight retouching for reproduction purposes). The third and the most intense burst showed three peaks of which the second was apparently the largest. Observations with the *C.R.P.L.* type C_3 ionosphere recorder of this Observatory indicated neither a fade-out nor a marked ionospheric disturbance. The records of our magnetographs (Watson and La Cour) show that the period February 22–March 4 was far from being magnetically quiet; it is therefore impossible to say whether the effects, if any, of the eruptive prominence were obscured or not. Although the sun was under almost continuous optical observation from 0200 hr. until 0730 hr. U.T. on February 26, no indication of a flare was noticed.

It is of interest to note in this context that a solar noise-burst in association with the eruptive prominence of August 7, 1950, was reported by Dodson and Donselman[3], of the McMath-Hulbert Observatory, about two years ago. But there are some important differences between their observations and those reported here. Dodson and Donselman's eruptive prominence was associated with an active sunspot group, whereas there is no evidence of such association in the case of the eruptive prominence of February 26, 1953. A still more significant difference between the two cases is that the noise-burst on 200 Mc./s. occurred when the 1950 prominence had risen to a height of 285,000 km. above the chromosphere, whereas in the case of the 1953 prominence our 100-Mc./s. record showed that the first noise-burst happened simultaneously with the beginning of the eruption, that is, at a moment when the prominence was still on the limb with its topmost parts about 50,000 km. above the limb. The two subsequent bursts occurred when the topmost parts of the prominence were about 140,000 km. and 184,000 km. respectively above the limb. Theoretical considerations indicate that 100-Mc./s. radiation cannot ordinarily escape from the sun unless it is generated at a level higher than 100,000 km. above the sun's surface. The second and third bursts observed in the present case are therefore consistent with present theory. The occurrence of the first burst suggests that perhaps in some yet obscure way the mechanism of eruption itself renders the supernatant atmosphere temporarily more transparent than usual.

Radio Observations at the Time of an Ascending Solar Prominence

Bursts of radio emission are known to be associated with only one type of catastrophic solar activity, namely, chromospheric flares. Radio emission data at the time of occurrence of another type of catastrophic phenomenon, an ascending prominence, are then of interest. The ascending prominence of February 26, 1953, described by Das in the accompanying communication, was observed visually in Sydney, and solar emission intensity records on 62, 98, 200, 600, 1,200, 3,000 and 9,400 Mc./s. were obtained at that time.

In the period February 24–28 three well-defined bursts, all of about five minutes duration, were recorded. The first burst at 2320 hr. (U.T.) on February 25 occurred before the prominence erupted. The second was observed on 62, 98 and 200 Mc./s. at 0450 hr. on February 26. It occurred at the time of eruption of the prominence. This burst was also noted at 100 Mc./s. by Das. The third, observed on 62, 98, 200 and 600 Mc./s. at 0630 hr., was the most intense and occurred at the end of the life of the prominence when the material was streaming back towards the sun.

Ionospheric and magnetic data for February 26 showed none of the ultra-violet effects normally associated with flares which could be distinguished above the moderate activity at the time. Also, as there were no sunspots in this period, it is most unlikely that the bursts were associated with flares.

To extend the investigation, a search was made of previous spectroheliograph records. Ascending prominences, each smaller than that under discussion, were observed at 0000 hr. on June 10 and 0500 hr. on July 4, 1952 (private communication from Dr. Giovanelli of the Division of Physics, Commonwealth Scientific and Industrial Research Organization). No radio emission was observed at these times.

It may be concluded that not all ascending prominences give radio emission, although the larger and more eruptive ones may do so. Further radio observations at the time of ascending prominences are therefore desirable.

AN ATTENUATED STRAIN OF THE MYXOMATOSIS VIRUS RECOVERED FROM THE FIELD

By DR. R. MYKYTOWYCZ

Wildlife Survey Section, Commonwealth Scientific and Industrial Research Organization, Canberra, Australia

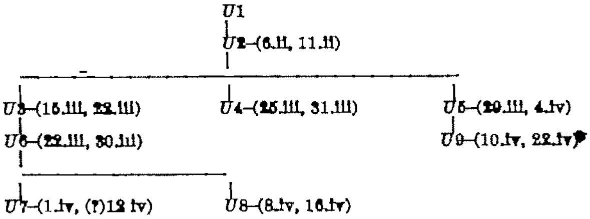
THE epizootic of myxomatosis described by Ratcliffe *et al.*[1], which is now in its third year and has spread to almost every rabbit-infested area in the south-eastern quarter of the Australian continent, was initiated with a strain of the virus that reached Australia from Brazil via the United States and Cambridge. It was the strain *B* of Martin[2], who has given an account of its history and characteristics. Throughout the lengthy experiments of Bull and Mules[3] the virus exhibited great stability and extraordinarily high lethality, death normally supervening on the 10th–12th day with a case mortality-rate of more than 99·5 per cent. My own experience with this strain of the virus has been in line with that of other workers, none of the three hundred odd rabbits (mostly of the wild type) infected with it having recovered.

During the early months of 1953, evidence was obtained by officers of the Wildlife Survey Section of the Commonwealth Scientific and Industrial Research Organization, working in collaboration with the Microbiology Department of the Australian National University, that there had been a significant decrease in the case mortality-rate of the disease in certain localities. The recovery, here recorded, of an attenuated strain of the virus from the field suggests that modification of the virus may be an important factor in the process of host–parasite adjustment that is apparently now taking place.

On February 6, two wild rabbits were brought into this laboratory from near Uriarra in the Australian Capital Territory. Myxomatosis was active at the time on the property from which the rabbits were obtained. It had been established in the immediate neighbourhood early in 1951, since when (augmented by further liberations) the infection had maintained itself in the Territory at a varying level of intensity. One of the two Uriarra rabbits was healthy; the other, a half-grown individual, had the appearance of being on the way to recovery from the disease. They were kept together in one cage. On February 15 the infected rabbit was found dead. In the interval, however, its condition had improved markedly, the eyes having opened and the swellings on the eyelids, the perineal region, and elsewhere on the body having subsided.

The second rabbit had developed symptoms of generalized myxomatosis on February 11; and when it was obvious that the disease was running an atypical and prolonged course, it was decided to passage the virus for further study. This rabbit (*U*2) was killed by a cage-mate on March 30, that is, forty-eight days after generalization.

The relation of the passages carried out is indicated in the diagram below. Infection was brought about in every instance by placing a healthy wild rabbit in a cage with a diseased animal, the period of contact ranging from 16 to 24 hours. The first date given is that of the contact, the second that of the appearance of the symptoms of generalization.



Not one of the eight animals infected with the virus from the original Uriarra rabbit has, to date (May 4, 1953), succumbed to the disease. In addition to the one killed by a cage-mate, one (*U*3) was sacrificed for serological study.

In four animals (*U*2, *U*4, *U*6 and *U*9) the onset of the disease was severe, typical symptoms developing and increasing up to about the tenth day after generalization. After that the swelling of the anus and the external genital organs regressed, leaving extensive scars; but the lesions of the eyelids, accompanied by discharge from the eyes, persisted for a considerable time. A point of interest was that rabbit *U*2 was found to be capable of passing on the infection throughout its prolonged illness, being in contact with U3 on the thirty-second, U4 on the forty-second, and U5 on the forty-seventh day after generalization.

The character of the disease in rabbits U5, U7 and U8 was very much milder. The eyelids and face developed discrete swellings, but no general oedematous enlargement. The eyes did not close, nor did they discharge. The perineal region did not become greatly swollen. Three weeks after generalization all swelling had subsided, scars only marking the sites of the larger tumours. The animals never lost condition, and remained fit enough to fight their cage-mates.

Rabbit U3 was outstanding in the mildness of its infection; in fact, myxomatosis could scarcely have been diagnosed from the clinical symptoms. Generalization was marked by a very slight inflammation of the eyelids, anus and preputium. Later, the only indication of lesions, which had produced no palpable swellings, were ruffled fur around the base of the ears and on the front of the face. When the animal was sacrificed eight days after generalization, the only signs of infection were numerous small lesions on the skin of the body, a very slight asymmetrical swelling of the genital organs, and some small tumours on the upper eyelids, the top of the nose, and at the bases of the ears.

The case-histories of the animals used in this study indicate that a modified strain of lowered virulence has appeared in the field. The possibility of all the experimental rabbits possessing an enhanced genetic resistance seems too remote for serious consideration: they were obtained from different parts of the Territory and, moreover, Prof. Fenner[4] reports that the Uriarra strain of the virus is producing an atypical disease in laboratory rabbits, which, of course, come from a population without a previous history of contact with the infection.

Two variants of the myxomatosis virus of greatly reduced virulence have appeared in the laboratory, Hurst's[5] neuromyxoma and Berry's[6] strain 80A. This is the first recorded recovery from an epizootic in a wild rabbit population of a strain of the virus modified to a degree comparable with these two laboratory variants. I have also indications, based on the observation of naturally infected rabbits, of the occurrence of atypical mild infections in two other localities within the Australian Capital Territory; and Fenner[7] now has evidence that somewhat attenuated strains may have appeared in the field in other parts of Australia. [May 4.

(*Note added in proof. July 21.*) Since the above report was written, the passaging, by contact infection, of the Uriarra 'strain' of the myxoma virus has been continued. Five more rabbits have made complete recoveries, while one animal (which proved to be heavily infected with coccidia) has succumbed. However, virus recovered from mild cases, and inoculated into test animals for various purposes, has failed to produce the non-lethal disease characteristic of the contact-infection series. Thus the overwhelming majority of the animals infected by mosquitoes that had fed on a rabbit inoculated with material from rabbit No. U3 have died, though these fatal infections have been rather atypical[8].

It is not easy to see how the mere difference in the mechanism of infection (that is, by contact—whatever this may involve—and by intradermal inoculation or mosquito bite) could provide a satisfactory explanation of these contrasting results. It has been suggested[9] that the Uriarra 'strain' is a mixture of strains including a variant of low virulence, the complex character of which has somehow been maintained through the series of contact infections. Information on the behaviour of infections by more than one strain of the myxoma virus appears to be limited to the results of some experiments by Dr. L. B. Bull[10], who used Martin's strain *B* and Hurst's neuromyxoma. The disease produced was mild, although only fully virulent virus was recovered from the animals that had been simultaneously infected by both strains.

EXPLOSIONS IN MIXTURES OF HYDROGEN, CHLORINE AND NITROGEN TRICHLORIDE

By Dr. P. G. ASHMORE

Department of Physical Chemistry, University of Cambridge

It is well known that nitrogen trichloride will inhibit the photochemical reaction between hydrogen and chlorine when the total pressure of the reactants is about atmospheric. We have recently shown, on the other hand, that at low pressures traces of nitrogen trichloride cause an explosive combination of the hydrogen and chlorine in the dark after an induction period. These low-pressure, low-temperature explosions have been examined by making up mixtures of nitrogen trichloride, chlorine and hydrogen, and of nitrogen trichloride, chlorine and nitrogen for comparison, at high pressures, and then admitting a selected pressure of the chosen mixture to an evacuated reaction vessel. This vessel was cylindrical, of internal diameter 30 mm., and was held in a thermostat and shielded from light. Explosions of mixtures of hydrogen, chlorine and nitrogen trichloride were accompanied by a bright flash and were audible; when nitrogen replaced the hydrogen, the explosion was extremely faint, but a sharp kick was registered on the Bourdon gauge and was attributed to the explosive decomposition[1] of the nitrogen trichloride. Whenever slow decomposition of the nitrogen trichloride occurred, it was followed by the accompanying pressure change due to the overall reaction: $2NCl_3 \rightarrow N_2 + 3Cl_2$. After a reaction in mixtures of hydrogen, chlorine and nitrogen trichloride, the gases were withdrawn through spirals surrounded with liquid nitrogen, so that the amount of hydrogen chloride formed could be estimated.

The nitrogen trichloride was prepared by running excess of chlorine into a mixture of ammonia and hydrogen or nitrogen. The addition of the hydrogen or nitrogen keeps the pressure above the upper limit

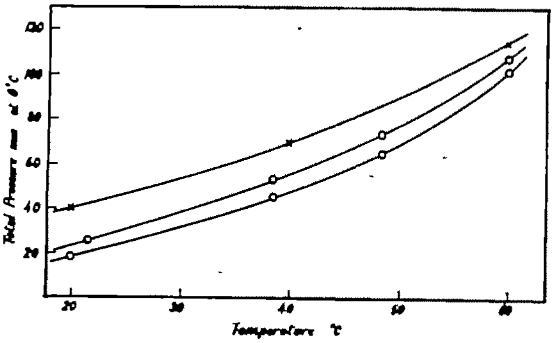

Fig. 1. Variation of the upper limit of ignition with temperature. Bottom curve for equimolar nitrogen and chlorine, middle curve for equimolar hydrogen and chlorine, each with about 1 per cent nitrogen trichloride; the top curve gives Apin's values for nitrogen trichloride alone

for explosion at room temperature (see Fig. 1), so preventing the ignitions sometimes observed[1] when chlorine is run into ammonia alone. Very little of the hydrogen used as a diluent was converted to hydrogen chloride; this result would be expected from the molecular mechanism usually postulated for the reaction: $4NH_3 + 3Cl_2 \rightarrow NCl_3 + 3NH_4Cl$.

The principal results observed were as follows:

(1) Explosions occur in both the hydrogen, chlorine, nitrogen trichloride system and the nitrogen, chlorine, nitrogen trichloride system below a reproducible pressure (the upper limit). Experiments were not made to investigate any possible lower limit.

(2) The upper limit appears to be independent of the proportion of nitrogen trichloride in the mixtures, once this is above 0·1 per cent, up to the highest proportion used (2·0 per cent).

(3) The upper limit varies with temperature as shown in Fig. 1, where the curves for hydrogen plus chlorine and for nitrogen plus chlorine in the presence of 1 per cent of nitrogen trichloride are compared with the curve for nitrogen trichloride alone as determined by Apin[2].

(4) Below the upper limit, the hydrogen and chlorine in mixtures of hydrogen, chlorine and nitrogen trichloride are converted completely to hydrogen chloride; immediately above, the proportion converted falls abruptly to zero. In nitrogen, chlorine, nitrogen trichloride mixtures, the nitrogen trichloride decomposes explosively and completely at pressures below the upper limit.

(5) For both mixtures the rate of decomposition of the nitrogen trichloride at pressures just above the upper limit follows an *S*-shaped curve; as the total pressure increases, the maximum rate falls off very rapidly and the time elapsing before the maximum rate is reached increases greatly. Typical results are shown in Fig. 2.

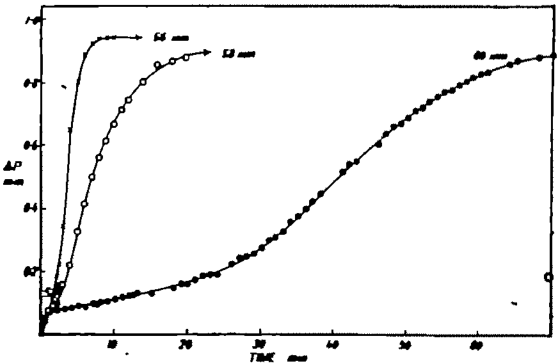

Fig. 2. Increase of pressure due to the slow decomposition at 38·4° C. of nitrogen trichloride in the presence of equimolar mixtures of hydrogen and chlorine at pressures (shown in mm. at 0° C.) just above the upper limit (55 mm.)

(6) There is an induction period before all explosions which presumably corresponds to the time taken by the decomposition of the nitrogen trichloride to reach its maximum rate. The induction period increases rapidly but smoothly as the pressure increases through the upper limit.

(7) Traces of nitrosyl chloride eliminate the explosions in hydrogen, chlorine, nitrogen trichloride and in nitrogen, chlorine, nitrogen trichloride mixtures. This is probably due to rapid reactions such as:

$$NOCl + Cl \rightarrow NO + Cl_2,$$

which remove the chain centres responsible for the explosive decomposition of the nitrogen trichloride.

(8) A few runs with methane in place of hydrogen showed that it was chlorinated rapidly below an upper pressure limit; there was no visible ignition, but there was a very strong kick on the Bourdon gauge.

The parallel behaviour of the systems hydrogen, chlorine, nitrogen trichloride and nitrogen, chlorine, nitrogen trichloride suggests that the explosive combination of the hydrogen and chlorine is triggered by centres provided by the thermal decomposition of the nitrogen trichloride. In order to account for the upper limits observed in these experiments and by Apin, the thermal decomposition must be assumed to proceed by a branched-chain mechanism. Norrish and Griffiths[1] suggested that the chlorine-photosensitized decomposition involved the propagating steps:

$$Cl + NCl_3 \xrightarrow{k_2} NCl_2 + Cl_2$$

and

$$NCl_2 + NCl_3 \xrightarrow{k_3} N_2 + 2Cl_2 + Cl,$$

and the terminating step

$$Cl + NCl_3 + M \xrightarrow{k_T} NCl_4 + M.$$

In the thermal decomposition, the chain-initiating step is probably:

$$NCl_3 \xrightarrow{k_1} NCl_2 + Cl.$$

This is followed by the two propagating steps, the the second of which is highly exothermic and might occasionally take the course

$$NCl_2 + NCl_3 \xrightarrow{k_B} N_2 + Cl_2 + 3Cl$$

and so give positive branching. The competition between reactions k_B and k_T leads to an upper pressure limit P_U given by:

$$P_U\,(k_T' f' + k_T'' f'' + \ldots) = k_B \frac{k_1}{k_2},$$

where f', f'', etc., are the mole fractions of the gases in the mixtures and k_T', k_T'', etc., the corresponding velocity constants for the chain-terminating steps. The upper limit is thus independent of nitrogen trichloride, as observed experimentally, but varies with the composition of the mixture.

I am grateful to Prof. R. G. W. Norrish and to Prof. F. S. Dainton for many stimulating discussions about this work.

Hæmoglobin in Protozoa

The presence of hæmoglobin in the ciliate *Paramecium caudatum* was discovered by Sato and Tamiya[1]. This is the first, and so far the only, record of the occurrence of hæmoglobin in Protozoa, one of the largest phyla of the animal kingdom.

In the course of our study of the structure and properties of cytochrome in micro-organisms, we were able to confirm Sato and Tamiya's observations on *Paramecium*, to extend them to another ciliate *Tetrahymena* (*Glaucoma*) *pyriformis*, and to determine the concentration of hæmoglobin in both ciliates. Our study of *Paramecium caudatum* was based upon cultures of this ciliate kindly provided by Dr. P. N. Ganapati. The ciliate was cultivated for 14 days at 24° in a bacteria-free medium containing a suspension of the yeast *Torula utilis* in half-saturated calcium sulphate solution. A suspension of *Paramecium* freed from yeast was concentrated by centrifugation; the supernatant fluid was rapidly decanted leaving a cake of ciliates which was pink by reflected light and distinctly red by transmitted light. Spectroscopic examination of a well-aerated suspension of this ciliate showed two strong absorption bands of oxyhæmoglobin at about 582 and 545 mμ which, when aeration was interrupted, disappeared and were replaced by the bands of the reduced components of cytochrome. In an aerated suspension treated with cyanide the α-band (582 mμ) of oxyhæmoglobin could be seen together with the bands of the reduced components of cytochrome, while the β-band (545 mμ) was somewhat modified by the appearance of the α-band of cytochrome *c* (550 mμ). On passing through the suspension a current of a gas mixture $CO/O_2 = 4$, the bands of oxyhæmoglobin were replaced by two more diffuse but still very distinct bands of CO-hæmoglobin lying at about 574 and 539 mμ. When the current of gas mixture was interrupted, the band at 574 mμ remained visible together with the bands of reduced cytochrome. On treating the suspension of *Paramecium* with an oxidizing agent such as quinone, the absorption bands of oxyhæmoglobin disappeared and were replaced by the weak band at 635 mμ of acid methæmoglobin.

In a similar way we were able to demonstrate the presence of hæmoglobin in another ciliate, *Tetrahymena pyriformis* (GL.), the strain of which was kindly supplied by Dr. E. G. Pringsheim. This was the strain described by Lwoff[2] under the name of "*Glaucoma piriformis*" and reclassified by Corliss[3]. The organism was cultivated at 30° in two to four litres of sterile medium containing 1 per cent peptone and 0·4 per cent sodium chloride, harvested after six days of growth, using a small angle centrifuge, and resuspended either in 0·45 per cent sodium chloride or in Ringer-phosphate solution[4]. Aerated suspensions of *Tetrahymena* showed a weak but distinct α-band of oxyhæmoglobin at about 582 mμ which was somewhat masked by the absorption bands of cytochrome. The formation of carbon monoxide hæmoglobin and of methæmoglobin was recognized by the disappearance of the bands of oxyhæmoglobin in the presence of carbon monoxide or quinone respectively, rather than by the appearance of the characteristic bands of these derivatives. It may be noted that Baker and Baumberger[5], who studied the absorption spectrum of cytochrome in *Tetrahymena geleii* (*Tetrahymena pyriformis* (T.)[3]), failed to record the presence of hæmoglobin in this ciliate. However, the fact that they refer to the observations of Sato and Tamiya on hæmoglobin in *Paramecium* suggests that either hæmoglobin was completely absent in their cultures of *Tetrahymena* or present in much too low concentration to be easily recognized.

The concentration of oxyhæmoglobin in *Paramecium* and *Tetrahymena* was determined by comparing the intensity of their absorption bands with those of a standard solution of oxyhæmoglobin. A flat-bottomed tube containing a thick suspension of ciliates was placed on the stage of the microspectroscope; the tube was surrounded with ice to slow down the respiratory activity of the cells, and therefore the deoxygenation of hæmoglobin. A little tributyl citrate was added to the suspension to prevent frothing during aeration, and the absorption spectrum of oxyhæmoglobin in the tube was matched against that of a standard solution of oxyhæmoglobin placed in one of the compartments of a double wedge trough[6]. The hæmoglobin content of *Paramecium* was also estimated as the carbon monoxide hæmoglobin derivative, the absorption spectrum of which, although not as strong as that of oxyhæmoglobin, is nevertheless very distinct and more stable than the latter. Moreover, carbon monoxide protects hæmoglobin from slow oxidation to methæmoglobin. This method was not, however, applicable to the study of *Tetrahymena*, the hæmoglobin content of which was too low for the proper observation of its carbon monoxide derivative.

The hæmatin content of the ciliates was determined as pyridine hæmochromogen, the absorption bands of which were matched with a standard solution of pyridine hæmochromogen prepared from pure hæmin. Assuming that the equivalent weight of hæmoglobin in ciliates is about 17,000, the hæmoglobin content of *Paramecium* from several batches of culture gave values (on a dry-weight basis) varying between 1·12 and 1·74 per cent, which correspond to a hæmatin content of 0·043–0·067 per cent. On the other hand, the hæmatin content estimated as pyridine hæmochromogen was found to vary between 0·088 and 0·11 per cent; the excess of hæmatin thus estimated belongs to other hæmoproteins present in the cells.

The hæmoglobin content of *Tetrahymena pyriformis* (GL.) estimated as oxyhæmoglobin was found to vary between 0·22 and 0·3 per cent, which corresponds to a hæmatin content of 0·008–0·012 per cent, whereas the total hæmatin content estimated as pyridine hæmochromogen was found to be between 0·025 and 0·035 per cent.

The presence of hæmoglobin in two very common ciliates, *Paramecium caudatum* and *Tetrahymena pyriformis*, suggests the possibility that hæmoglobin may have a much wider distribution in Protozoa than was hitherto suspected. However, this problem can be solved only by careful spectroscopic examination of thick suspensions of these organisms. Unfortunately, pure mass-cultures of Protozoa are often very difficult to obtain.

This work was carried out while one of us (J. F. R.) held a Medical Research Council studentship.

Factors modifying the Influence of Light on Germination

Within the temperature-range of 20–30° C. a higher percentage of lettuce seeds, var. Grand Rapids, germinates after irradiation with red light within the range of 6000–7000 A. than in the dark. At about 18° C., in darkness, the percentage of germination is high and cannot be further increased by red light. Above 32° C. the percentage of germination is nil in darkness, and cannot be increased by red light. Within these temperature limits the maximum relative effect of red light on germination is reached at approximately 26° C. This phenomenon appears to be frequent among different species of seed, although the temperature-range within which the light-sensitivity of germination is exhibited varies with the species in question[1].

The effect of red light on germination can be counteracted by radiation of longer wave-length, between 7000–8200 A. As Borthwick, Hendricks and co-workers have shown[2], the maximum stimulating effect of red light occurs at about 6600 A., the maximum inhibiting effect of infra-red radiation at approximately 7300 A.

Recently, we proposed a mechanism[3] which might account for the known effects of light, temperature and possibly chemical agents (such as oxygen, coumarine and thiourea) on germination in so far as these effects are connected with the same mechanism, and attempted to find a connexion between these effects in the case of germination and in other biological processes where, as Kelner[4] and Dulbecco[5] have shown, similar effects occur.

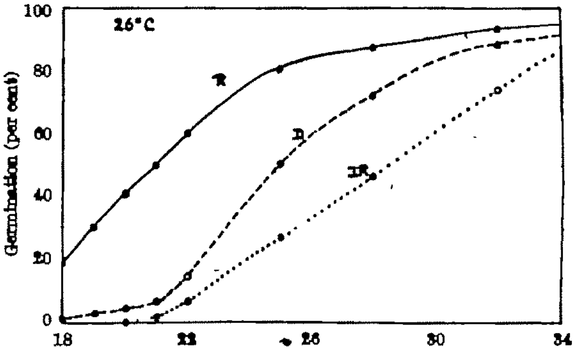
We have now investigated whether irradiation with the inhibiting infra-red light (IR) has an effect on seeds which have undergone imbibition in the dark and have not been treated with red light. As shown in Table 1, pretreatment with the infra-red light reduces the percentage of germination below that of the 'dark-control' (D) (that is, seeds germinating throughout in darkness). The percentage of germination thus reached is, within the experimental error, identical with the value obtained when seeds after imbibition in the dark are first stimulated with red light and then inhibited with infra-red. For comparison reference may be made to the results of others[6] who have shown that pretreatment with infra-red influenced the effect of ultra-violet or X-ray irradiation following on it, without having by itself an observable biological effect in those cases (for example, *Drosophila*, *Tradescantia* and *Aspergillus terreus*). In our case, also, when the increase in the percentage of germination due to the treatment with red light (R) is measured (that is, the values of (R minus D) and (R minus IR) respectively are compared) there is a relative increase in this effect of the red light after treatment with infra-red. In addition, one is able to point out the biological process directly affected by the infra-red in the present case.

Using infra-red irradiation either on 'dark' seeds or on those previously irradiated with red light, it was found that the percentage of germination may be lowered to one and the same limit, which is determined by the temperature at which the experiment is carried out. Using red light either on 'dark' seeds or on seeds pretreated with infra-red light, the percentage of germination may be raised to an upper limit, which is again a function of the temperature. These temperature-dependent limits are shown in Table 2.

Table 1. LETTUCE SEEDS, VAR. GRAND RAPIDS. PERCENTAGE OF GERMINATION AT 26° C.

D, 'dark-control'. imbibition and germination in dark; R, irradiation with red light interposed between imbibition and germination in dark; IR, irradiation with infra-red interposed; IRR, infra-red, followed by red, interposed; RIR, red, followed by infra-red, interposed

	D	R	IR	IRR	RIR
%	23 ± 5·2	76 ± 5·0	12 ± 3 7	72 ± 6·7	15 ± 5·8



Dependence of percentage of germination on time since imbibition. Percentages in terms of seeds germinating up to 48 hr. after imbibition. D, 'dark-controls'; R, irradiated with red light; IR, irradiated with infra-red light

Table 2. LOWER AND UPPER TEMPERATURE-DETERMINED LIMITS OF PERCENTAGE OF GERMINATION

Temp. ° C.	Lower limit (per cent)	Upper limit (per cent)
20	32 ± 5	88 ± 3
26	14 ± 3	74 ± 2
30	0 + 1	35 ± 6

One possible interpretation is that the existence of the two limits points to the operation of two mechanisms determining the percentage of germination. One of these mechanisms is not affected by light and operates up to the limit below which the percentage of germination cannot be reduced by light alone. The other mechanism is the light-sensitive one responding to the opposing effects of red and infra-red and operates up to the temperature-dependent upper limit beyond which germination cannot be increased by light alone. The effect of infra-red irradiation on 'dark' seeds is then due to the existence to some extent of the light-sensitive system in the 'dark' seeds, possibly owing to the fact that even before imbibition these seeds contain moisture in equilibrium with the moisture content of the air[7].

This view of two mechanisms leading to germination in the light-sensitive seeds is supported by the results shown in the graph, which indicate that the specific velocity of the germination process is higher in seeds which germinate as the result of the influence of irradiation with red light, and lower in those seeds germinating as the result of the light-independent process. The 'dark' seeds show a composite behaviour.

These results do not permit us to distinguish between the alternatives: whether the physicochemical system subject to the inhibiting effect of the infra-red is immediately related to the one produced by the action of the red light or separated from this step by additional intervening biochemical processes. Table 3 shows that the inhibiting effect of infra-red appears to be greatest when it is applied immediately after irradiation with red light, indicating the absence of intervening biochemical steps, and

Table 3. Effect of Delay in Applying Infra-red after Red on the Percentage of Germination

	Red alone	Infra-red applied t minutes after red				
		t	0	30	45	60
Per cent of germination	71		15	19	24	31

supporting the mechanism previously suggested[3] according to which it is the system formed by the action of the red light which is sensitive to the effect of the infra-red.

The full details of these and other related experiments will be published elsewhere.

Direct Deamination of Adenosine Diphosphate by Washed Myofibrils

The deamination of adenine nucleotides by homogenates and extracts of skeletal muscle is usually ascribed to the action of an enzyme, originally described by Schmidt[1], which specifically deaminates adenosine monophosphate. Direct deamination of adenosine triphosphate has not been demonstrated, though the work of Banga and Josepovits[2] suggested a simultaneous production of inorganic phosphate and ammonia from adenosine diphosphate. This effect required the presence of myosin plus a 'protin' preparation, and an isomer of adenosine diphosphate was postulated as an intermediate compound. This claim has been criticized adversely by Bailey[3].

Evidence supporting the possibility of a direct deamination of adenosine diphosphate has now been obtained. Muscular tissue (psoas, longissimus dorsi and thigh muscles) from the rabbit was used in these investigations. It was homogenized with a high-speed homogenizer to the myofibril-level, centrifuged, washed and recentrifuged repeatedly. For this procedure, 0·16 *M* potassium chloride, acetate buffer (0·2 *M*, *p*H 5·5) or borate buffer (0·1 *M*, *p*H 8·6) were all found to be suitable. The fibrils were finally suspended in acetate or veronal buffer (*p*H 5·5–6·0) and stored at 0° C.

Fig. 1 shows the effect of adding either (*a*) adenosine triphosphate, or (*b*) adenosine diphosphate to such a fibril suspension. With adenosine triphosphate, there is a rapid hydrolysis of the terminal phosphate group, followed by a slow dismutation of adenosine diphosphate due to residual myokinase acting at a *p*H well below its optimum. The production of ammonia

(*a*) Adenosine triphosphate added (13·9 μ*M*). (*b*) Adenosine diphosphate added (7·4 μ*M*). ○, Amino-nitrogen liberated. ●, Inorganic phosphate liberated

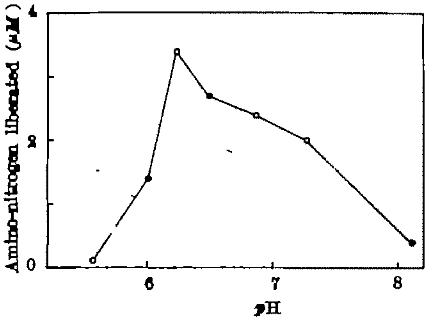

Fig. 3. *p*H activity curve for deamination of adenosine diphosphate in presence of versene (0·01 *M*). Muscle equivalent 0·63 gm., veronal buffer (0·03 *M*), adenosine diphosphate (7·4 μ*M*), 30 min. incubation at room temperature. (Liberated inorganic phosphorus found to be zero at all *p*H values)

begins slowly but rapidly increases as adenosine diphosphate is formed. At the end of the reaction period deamination is practically complete; but little more than half of the labile phosphate has been hydrolysed. This situation is consistent with the formation of inosine diphosphate (which is not dismuted by myokinase[4]), together with a small amount of inosine monophosphate by the combined action of myokinase and adenosine monophosphate-deaminase. When adenosine diphosphate is added originally, the washed fibrils cause a rapid and nearly complete production of ammonia, and a slow production of phosphate to the extent of approximately one-third of the labile phosphate.

In both these cases, it is suggested, direct deamination of adenosine diphosphate occurs, together with some dismutation. The end-product appears to be mainly inosine diphosphate, with small amounts of inosine monophosphate.

The techniques of paper chromatography and of paper ionophoresis have been used for checking the presence (or absence) of the various nucleotides at all stages of the reactions mentioned above. The results (see Fig. 2) confirm the interpretation already given of the curves shown in Fig. 1.

A fuller investigation of the direct deamination of adenosine diphosphate disclosed by these experiments is complicated by its dismutation caused by myokinase. The accompanying table shows the effect of *p*H on the relation between dismutation and deamination of adenosine diphosphate. Increase of *p*H from 5 to 7 progressively favours dismutation, and inosine monophosphate ultimately replaces the diphosphate as the main end-product. It was, however, found that 'versene' (ethylene diamine tetra-acetate), at a concentration of 0·01 *M*, prevented dismutation at all values of *p*H, without affecting deamination. In the presence of this reagent, the *p*H-optimum for the activity of adenosine diphosphate deaminase was found to be approximately 6·2 (see Fig. 3).

EFFECT OF *p*H ON RELATION BETWEEN DEAMINATION AND DISMUTATION OF ADENOSINE DIPHOSPHATE BY WASHED MYOFIBRILS. Muscle equivalent 0·6 gm., veronal buffer (0·03 *M*), adenosine diphosphate (10·3 μ*M*), room temperature. Reaction allowed to go to completion

*p*H	ΔP	ΔN	IMP formed (ΔP)	IDP formed (ΔN—ΔP)	Ratio $\frac{IDP}{IMP}$
5·1	2·5	9·1	2·5	6·6	2·6
5·4	3·6	9·3	3·6	5·7	1·6
5·9	6·7	9·3	6·7	2·6	0·4
6·2	7·6	9·6	7·6	2·0	0·3
7·0	10·3	9·8	10·3	−0·5	—

Expressed in μ*M*

It has proved impossible so far to measure the effect of calcium and magnesium ions on the deamination of adenosine diphosphate, because these ions, particularly magnesium, progressively stimulate dismutation as their concentration is increased up to 0·005 *M*. Cysteine (0·01 *M*) is found to activate deamination strongly, iodoacetate (0·01 *M*) has little effect, while fluoride and selenite (0·01 *M*) halve its activity.

Homogenized, washed rabbit heart muscle does not exhibit adenosine diphosphate-deaminase activity, neither do preparations of actin or myosin.

Influence of Cysteinamine, Methylamine and Cortisone on the Toxicity and Activity of Nitrogen Mustard

ACCORDING to Bacq and Herve[1,2], cysteinamine (2-mercaptoethylamine) and methylamine protect mice against a lethal dose of X-irradiation. The amines prevent death, but do not inhibit X-ray damage to the testes. It was tempting, therefore, to see whether they reduce the toxicity of a 'radiomimetic' drug[3] without at the same time reducing its specific activity. Colter and Quastel[4] have already shown that, *in vitro*, methylamine protects choline oxidase against nitrogen mustard.

On the first day of the experiment, female rats of 51 ± 5·8 gm. mean body-weight received a subcutaneous transplant of Walker carcinosarcoma. Treatment was started on the second day with various doses, per 100 gm. body-weight, of methyl-*bis*-(2-chloroethyl)amine hydrochloride (*HN*2) given intraperitoneally in 0·4 ml. of distilled water. In each experiment approximately half of the animals were given previous injections of cysteinamine, methylamine or cortisone acetate. The cysteinamine and methylamine were given intraperitoneally in 0·2 or 0·3 ml. of distilled water per rat, the solution being made up immediately before use. A suspension of 0·125 gm. of cortisone acetate (cortone acetate) was injected subcutaneously twice a day with an interval of six hours between injections. The nitrogen mustard was given half-way between the two injections. All rats received ten daily injections of *HN*2, intervals being allowed on Sundays, or, in imitation of clinical timing, four daily injections with a day's interval after the third injection. On the fourteenth day, the tumours and other tissues were dissected. The mean weight ratios between untreated and treated tumours were used as a measure of activity of the nitrogen mustard.

The results are shown in the table. Rats injected with *LD*100 of *HN*2 died even when they had received cysteinamine three hours previously. When, however, the interval between the injection of cysteinamine and mustard was reduced to half an hour, 50 per cent protection was afforded.

*HN*2 is more toxic to tumour-bearing than to normal rats[5]. When injected, for example, with a daily dose

TOXICITY AND ACTIVITY OF METHYL-*bis*-(2-CHLOROETHYL)AMINE HYDROCHLORIDE (*HN2*) ALONE AND AFTER COMBINED TREATMENT

HN2 (mgm./kgm./day)	Addition agent	Treatment (mgm./rat/day)	Interval between injections (hr.)	Duration of treatment (days)	No. of deaths		Tumour-inhibiting activity		
					Combined	*HN2*	Combined treatment (ratio)	*HN2* only (ratio)	Significance of the difference (*P*)
1·0	Cysteinamine	2·5	3	4	12/12	12/12	—	—	—
1·0	,,	2·5	1/2	4	6/12	12/12	—	—	—
0·5	,,	2·5	3	4	0/10	4/10	63·9	22·1	$< 0.05 > 0.01$
0·5	,,	2·5	3	4	1/11	5/11	17·1	18·6	—
0·2	,,	3·0	6	10	0	0	51·7	7·5	< 0.01
0·2	,,	3·0	6	10	0	0	42·0	5·9	< 0.01
0·5	Methylamine	2·0	3	4	4/11	4/10	14·1	22·1	0·6
0·2	,,	2·0	6	10	0	0	10·4	6·4	0·3
0·5	Cortone	0·25	3	4	10/12	4/10	—	22·1	—

of 0·5 mgm./kgm. on four days, normal female rats survived the fourteen days period of the test, whereas a number of tumour-bearers died. However, when this dose was administered three hours after an injection of cysteinamine, protection amounting to almost 100 per cent was afforded.

The tumour-inhibitory activity of *HN2* was not reduced by the supplementary use of cysteinamine; on the contrary, in one duplicate test the activity of the mustard seemed to be increased. In a further duplicate experiment in which cysteinamine was given six hours before a non-lethal dose of *HN2*, the use of the combined treatment resulted in a sevenfold increase in the tumour-inhibitory activity of *HN2*. This potentiation of the tumour-inhibitory effect was accompanied by an 18–41 per cent greater effect of *HN2* on the spleen-weight. Cysteinamine *per se* (104 mgm./kgm. distributed over ten daily injections) caused shrinkage of the spleen (45 per cent, $P < 0.01$) but no inhibition of tumour-growth.

The adrenals of tumour-bearers treated with cysteinamine showed an increase of cortical lipoid as compared with untreated controls, whether the compound had been injected alone or before the *HN2*. In the dose administered, methylamine influenced neither the toxicity of *HN2* nor its effect on tumour-growth and spleen-weight. Cortisone, which is known to increase the toxicity of X-irradiation in mice[6], likewise increased the toxicity of *HN2* considerably.

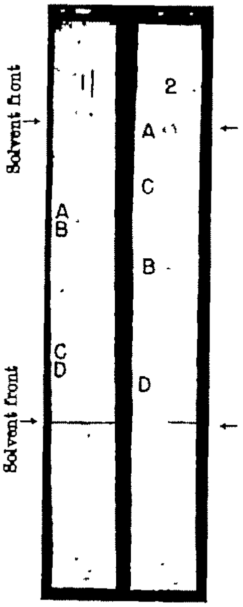
Chromatographic Separation, using Chemically Treated Paper, of Aldehydes and Ketones on the Basis of their Reactivity

WE have, for some time, been interested in the separation and identification of materials resulting rom the alkaline oxidation of waste sulphite liquor. Chromatography has been used extensively for separating and identifying these materials; but until now it has not been possible to effect a complete eparation of vanillin and acetovanillone on paper.

A short time ago we realized that a separation might be effected if the filter paper was modified by spraying it with a sodium bisulphite solution, since aldehydes are more reactive than ketones with bisulphite and the distribution coefficient of an aldehyde would thus be altered more than that of a ketone. The aldehyde would then tend to be more retarded on the paper than the ketone. αβ-Unsaturated ketones, in which the carbonyl activity is decreased, should scarcely be retarded at all.

We have sprayed filter paper with a dilute sodium bisulphite solution and after drying the paper have applied a mixture of vanillin, acetovanillone, veratraldehyde and acetoveratrone. These materials were also applied to an untreated paper. The papers were developed for one hour with the organic phase produced by mixing hexane (9 vol.) chloroform (1 vol.) and water (10 vol.). In the case of the untreated paper no separation of vanillin and acetovanillone or veratraldehyde and acetoveratrone was effected, although the first two compounds were separated from the latter two. On the treated paper the four materials were completely separated; the acetoveratrone had the highest R_F value followed, in order, by acetovanillone, veratraldehyde and vanillin (see accompanying illustration).

A particularly interesting feature of the use of such treated papers is the information which may be obtained regarding the functional groups in unknown



(*A*) Vanillin; (*B*) acetovanillone; (*C*) veratraldehyde; and (*D*) acetoveratrone. Paper 1, untreated; paper 2, treated with sodium bisulphite solution. Both papers were developed for one hour with hexane–chloroform–water and sprayed with 2,4-dinitrophenylhydrazine in hydrochloric acid solution compounds. Thus, on a bisulphite-treated paper a carbonyl compound may be immediately identified as having a carbonyl activity similar to that of an aldehyde or ketone.

Following our success with aldehydes and ketones, papers treated with other chemicals were considered for the identification of different functional groups in compounds. It is a well-known fact that buffered papers have been used for the separation of acids or bases[1–4]. Such papers also provide a convenient and rapid method for distinguishing between non-acids, phenols and stronger acids. For example, using a paper treated with sodium carbonate (and the hexane solvent mentioned above), vanillin, which is a phenol and therefore acidic, remains on the starting line of the chromatogram and is distinguished from veratraldehyde which is non-acidic and moves down the paper. Also, by the use of paper treated with a solution of disodium hydrogen phosphate, vanillic acid, a carboxylic acid, remains on the starting line of the chromatogram and is distinguished from vanillin, which is phenolic and moves down the paper.

In all cases it is important to use a sufficiently active solvent for development of the chromatogram, since no conclusions concerning the chemical constitution of a material can be drawn from treated paper if the substance does not move on untreated paper. Thus, for the chromatogram with vanillic acid mentioned above, it was necessary to use water-saturated benzene as solvent.

Preliminary work using bisulphite-treated papers indicates that the method may prove useful in the field of sugar chemistry.

We wish to thank the Research Council of Ontario and the Howard Smith Paper Company for permission to publish this work.

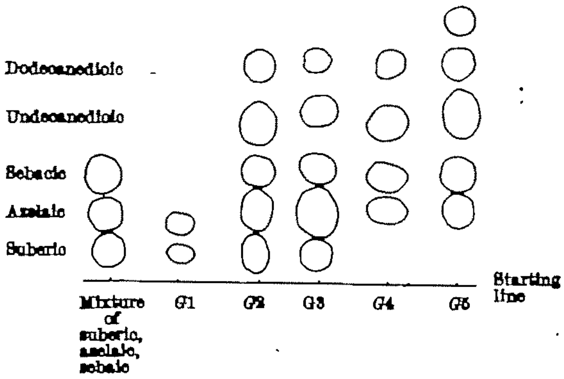
Iso-Oleic Acids in Cow and Buffalo Milk Fat

Phatak, Mahadevan and Patwardhan[1] have demonstrated the presence of four geometrical isomers of oleic acid in the *iso*-oleic acids fraction obtained from gradually hydrogenated groundnut oil. They used the method of Hilditch and Vidyarthi[2] for the oxidation of *iso*-oleic acids and separation of dibasic acids formed in the reaction. The dibasic acids were identified by paper chromatography according to the method of Reid and Lederer[3]. Four C_{18} monoethenoid acids with double bonds at Δ^{-8}, Δ^{-10}, Δ^{-11} and Δ^{-12}, respectively, in addition to elaidic acid, were thus shown to be present.

Partially hydrogenated groundnut oil is widely used in India as an adulterant of ghee (clarified butter). As the only C_{18}-monoethenoid acids present in butter so far known are oleic and vaccenic acids, it was felt that it should be possible to detect adulteration with hydrogenated oil by paper chromatography of the dibasic acids obtained on oxidation of the suspected product.



Chromatogram of dibasic acid fractions obtained by oxidation of solid fatty-acids from cow ghee

As a first step, ghee prepared from genuine cow milk fat was submitted to permanganate oxidation and separation of dibasic acid fraction according to the method of Hilditch and Vidyarthi[2]. The dibasic acids were then subjected to paper chromatography as described earlier. To our surprise, we found spots for suberic, azelaic, sebacic, undecanedioic and dodecanedioic acids on the paper chromatogram. Duplicate experiments with other samples confirmed these findings both in cow and buffalo butter fat. In a typical experiment with samples obtained from the Indian Dairy Research Institute, Bangalore, 330 gm. butter fat was saponified and the total fatty acids subjected to the lead-salt separation method as described by Hilditch. The solid fatty acids from the insoluble lead salts (158 gm.) were converted into their methyl esters. The acetone permanganate oxidation of the latter and the resolution of the products gave 4·1 gm. of dicarboxylic acids. These were converted into methyl esters and separated into five fractions by fractional distillation in vacuum. Ammonium salts of the free acids obtained on hydrolysis of the fractions were subjected to paper chromatography. The accompanying figure illustrates a tracing of spots obtained with these fractions; spots obtained by applying solutions of ammonium salt of pure dibasic acids are also included. The chromatogram for fraction *G*-5 gives an additional faint spot higher than the rest.

According to Begeman *et al.*[4], there exists a possibility of secondary production of other dicarboxylic acids during permanganate oxidation i acetone solution. They find that with the use o acetic acid as solvent the amount of these by-product is much reduced. In view of this, another sample o butter fat was submitted to permanganate oxidatio as described above, but in glacial acetic acid solution On separation of the dibasic acids fraction an chromatography, spots identical with those shown i the figure were obtained.

The chromatographic identification of the fiv dibasic acids leads to the conclusion that, in additio to oleic acid, other octadecanoic acids with doubl bonds at Δ^{-8}, Δ^{-10}, Δ^{-11} and Δ^{-12} exist in cow an buffalo butter fat. Of these, vaccenic acid, whic on oxidation would yield undecanedioic acid, wa already known to occur in cow butter fat[5]. Th other dibasic acids identified on the chromatogra are not likely to be derived from C_{10-18} monoethenoi or C_{18} diethenoid acids in butter fat, for it has bee shown that all of them, on oxidation, yield onl azelaic acid[6]. Whether they can be so derived fro

C_{20-22} unsaturated acids, the presence of which in butter fat has been demonstrated by Shorland and Johannesson[7], is not quite certain. The available evidence would, however, point to the positional isomers of oleic acid being the possible source of the dibasic acids identified in this investigation.

Further details of this work, which was supported by a grant from the Council of Scientific and Industrial Research, New Delhi, and the significance of our findings, will be described elsewhere. We are indebted to Mr. G. Ford, of the Hindustan Vanaspati Manufacturing Co., Ltd., Bombay, for the gift of pure dibasic acids.

Utilization of Purines for Nucleic Acid Synthesis in Man

THE utilization of purines by various species ranges from a utilization of adenine for the synthesis of both polynucleotide adenine and guanine and the utilization of guanine for polynucleotide guanine synthesis only[1], to the utilization of guanine for both polynucleotide adenine and guanine synthesis and the utilization of adenine for polynucleotide adenine only[2]. Between these contrasting patterns there exists a range of qualitative differences among various species[3].

These differences in the purine metabolism pattern of varying species made it desirable to obtain information on the utilization of purines in man and, if possible, to determine patterns of purine utilization by different cell types. This communication is an account of *in vitro* and *in vivo* studies made for this purpose.

Leucocytes, from patients with acute myeloid leukæmia, separated from red cells by the use of 'Dextran', were incubated in homologous plasma in siliconed flasks at 37° C. with carbon-14 labelled purines for four hours. Standard procedures were used for separating ribose nucleic acid and deoxyribose nucleic acid from the cells and for isolating and determining the radioactivity of individual purines. It was found that adenine-8-carbon-14 was incorporated into ribose nucleic acid adenine and transformed into deoxyribose nucleic acid guanine but not into the purines of the deoxyribose nucleic acid. The ribose nucleic acid adenine and guanine isolated from the leucocytes of one patient had a specific activity relative to the proffered labelled adenine of 15 and 5 per cent, respectively. The relative specific activities of ribose nucleic acid adenine obtained with leucocytes from two other patients were 10 and 2 per cent.

Leucocytes from another patient with acute leukæmia were incubated in separate experiments with adenine-8-carbon-14 for one, two, three and four hours, with guanine-8-carbon-14 for four hours and with 2,6-diaminopurine-2-carbon-14 for four hours. Adenine was utilized for the synthesis of ribose nucleic acid adenine and lack of aeration diminished this utilization; guanine and 2,6-diaminopurine were incorporated equally efficiently into ribose nucleic acid guanine. After four hours the activity of the nucleic acid purines was approximately 2 per cent of the activity of the purines added to the medium; at this time there was a suggestion that transformation into the other nucleic acid purine had occurred, that is, adenine was converted into ribose nucleic acid guanine, and guanine and 2,6-diaminopurine were converted into ribose nucleic acid adenine.

Adenine-8-carbon-14 (200 µC.) was given intravenously to a patient with chronic lymphatic leukæmia. Ribose nucleic acid and deoxyribose nucleic acid were isolated from leucocytes collected at intervals following the injection. It was found that adenine was incorporated into polynucleotides as ribose nucleic acid adenine and to a smaller extent as deoxyribose nucleic acid adenine, and that there was an appreciable transformation of the adenine into ribose nucleic acid and deoxyribose nucleic acid guanine. Activity of the ribose nucleic acid appeared to reach a maximum at day 5 (with an activity 710 counts/min./µM., or 0·7 per cent of the activity of the material administered) and in the deoxyribose nucleic acid at day 7 (with an activity of 130 counts/min./µM.). Full details of these studies will be published elsewhere.

I wish to thank Drs. C. Chester Stock and George Bosworth Brown for their encouragement and advice, Dr. M. E. Balis for supplying carbon-14 adenine and guanine, and the Chemotherapy Service, Memorial Center, for their co-operation. This investigation was aided by a grant from the National Cancer Institute of the United States Public Health Service.

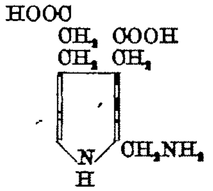
Structure of Porphobilinogen

WE recently described a number of reactions of porphobilinogen, from which we concluded that it has the structure (I); but it was not then possible to eliminate the alternative structure in which the positions of the two β-substituents are reversed[1].

Dehydration of porphobilinogen by acetic anhydride and pyridine gave a lactam which was represented by (II) or possibly (III). This ambiguity has now been resolved by cyclization of the lactam to the ketone (IV) by means of polyphosphoric acid, thus proving that our formulation (I) of porphobilinogen is correct.

The tricyclic ketone (IV) crystallized from water in prisms which began to decompose above 330° without melting (found: C, 63·35; H, 5·4; N, 14·7. $C_{10}H_{10}O_2N_2$ requires C, 63·2; H, 5·3; N, 14·7 per



(I)

(IV)

cent). Its absorption maximum in the ultra-violet (284 mμ, ε 20,600 in ethanol) is at a shorter wave-length than that of an α-acetyltrialkylpyrrole—an effect which is also observed in model pyrroles containing a 5-membered cyclic ketone. The infra-red spectrum of the keto-amide supports the structure (IV), although it would not have by itself provided conclusive proof, owing to strong hydrogen bonding and to partial overlap of the two carbonyl stretching frequencies.

This work forms part of a programme under the general direction of Prof. C. Rimington, whose interest and advice are gratefully acknowledged. We will report our results in full in the near future.

The 'Protactinyl' Ion

A VERY simple technique has been described by J. D. H. Strickland[1] for determining the charge of an ion in aqueous solution, which is applicable to radioactive tracer concentrations. The method involves competition for sites on mono-functional ion-exchange resins between the ion in question and varying amounts, in very large excess, of another ion of known charge.

This technique has been applied to the determination of the charge of the protactinium ion in dilute perchloric acid solution using trace amounts of protactinium-233. Dilute solutions of perchloric acid were prepared in the range of 0·1–3 *M*. About a million disintegrations per minute of protactinium-233 and 0·1 gm. 'Amberlite' *IR* 120 (hydrogen form) cation resin were added to 5 ml. volumes of acid in stoppered tubes. The mixtures were mechanically shaken for about two hours and then centrifuged to separate the resin 'fines'. Aliquots of the stock protactinium solution and of the perchloric acid solutions at equilibrium were taken for protactinium assay. The protactinium on the resin was obtained by difference. A plot of the ratio of the protactinium in solution to that on the resin at equilibrium against the acidity on double logarithmic paper gave a straight line of approximately unit slope. Therefore, the charge on the protactinium ion in dilute perchloric acid is + 1.

If protactinium is a member of a second rare-earth series, the actinides[2], its pentavalent ion should be similar to those of other members of this group—for example, UO_2^+, NpO_2^+ (ref. 3) and PuO_2^+ (ref. 4). As a charge of + 1 has now been found for protactinium, it seems probable that the ion present is PaO_2^+ and not PaO^{3+}, as it should be by analogy with vanadium and niobium in the same periodic group. Since a hexavalent state of protactinium is most unlikely, as the stable rare-gas electronic structure of radon would have to be opened up, it is safe to call this ion 'protactinyl' to distinguish it from protactinium 'penta' and 'tetra' compounds.

Full details of this work will be published later together with the work, at present in progress, for determining the range of hydrogen-ion concentration over which this ion is stable. Thanks are due to the Chief Scientist, Ministry of Supply, for permission to publish this note.

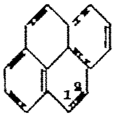
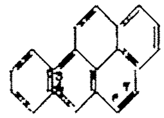
Bond-Orders in Aromatic Compounds

THE most satisfactory measure of the 'character' of a bond in an aromatic compound is probably given by its 'bond-order'[1]. Although this is a theoretical quantity, its significance is demonstrated by its relationship to bond-length[1] and to other bond properties which can be measured experimentally. It has also been shown[2,3] that there is a smooth-curve relationship between bond-orders and the 'corrected'[4] redox potentials of the corresponding *o*-quinones. As redox potentials can be measured fairly readily, this relationship offers a method whereby certain bond-orders can be evaluated experimentally.

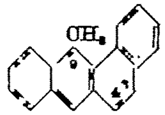
The method has now been examined with pyrene (I) and 3 : 4-benzpyrene (II). The character of the 6 : 7 bond in 3 : 4-benzpyrene may be of importance in connexion with the carcinogenic activity of the molecule, and it therefore seemed of interest to evaluate its bond-order from the redox potential of 3 : 4-benzpyrene-6 : 7-quinone[5]. At the same time, the bond-order of the 1 : 2 bond in pyrene has been evaluated from the redox potential of pyrene-1 : 2-quinone[6].



(I)



(II)



(III)

The experimentally observed redox potentials were 'corrected' in the usual way[4], and the results are summarized in the accompanying table. Redox potentials for phenanthra-9 : 10-quinone and for

1 : 2-benzanthra-3 : 4-quinone were also determined, and the results are in excellent agreement with the values given in the literature[4,7].

For the 1 : 2 bond of pyrene, the bond-order derived from the bond-order – redox potential relationship is estimated to be 1·766, in good agreement with the value (1·777) calculated by the method of molecular orbitals[8]. Similarly, the bond-order of the 6 : 7 bond in 3 : 4-benzpyrene is estimated to be 1·778.

It is not possible to evaluate bond-orders in substituted aromatic compounds in this way, but the redox potential of 9-methyl-1 : 2-benzanthra-3 : 4-quinone indicates that the 3 : 4 bond in 9-methyl-1 : 2-benzanthracene (III) must have a greater charge than in 1 : 2-benzanthracene itself, in agreement with theoretical predictions[9].

Quinone	Redox potential			
	Observed in 75 per cent alcohol	Estimated for 95 per cent alcohol	Corrected (this work)	Corrected (literature values)
Phenanthra-9 : 10-quinone	0·402	0·466	0·416	0·410
1 : 2-Benzanthra-3 : 4-quinone	0·426	0·430	0·380	0·380
9-Methyl-1 : 2-benzanthra-3 : 4-quinone	0·406	0·410	0·360	—
Pyrene-1 : 2-quinone	0·470	0·474	0·424	—
3 : 4-Benzpyrene-6 : 7-quinone	0·437	0·441	0·391	—

The potentials were determined by a polarographic procedure developed by one of us[10]. The quinone was dissolved in a buffer 0·1 *M* in sodium acetate and 0·1 *M* in acetic acid in a solvent (approximately 75 per cent alcohol) consisting of three parts of 95 per cent alcohol and one part of water. The polarogram was obtained with the dropping mercury electrode as cathode and the saturated calomel electrode as reference anode. The difference between the applied e.m.f. at the half-wave point and the e.m.f. of a cell consisting of the hydrogen electrode in the buffer alone versus the calomel electrode gave the standard redox potential of the system. The justification of this procedure has recently been given independently by Coulson and Crowell[11].

Spectrophotometric Determination of Amino-Groups

THE coupling of proteins with diazonium compounds has been studied extensively and has important applications in immunology and other fields; but the attention of investigators of the coupling mechanism has tended to be diverted from the role of the amino- and imino-groups by the brilliant red and orange-red colours produced by histidine and tyrosine, free or in peptide linkage. Busch, Patrascanu and Weber[1] have, however, isolated the colourless compound formed upon reaction of glycine with benzene diazonium chloride and have postulated the structure $HOOC.CH_2.N(N = N.C_6H_5)_2$. Eagle and Vickers[2] have shown that the amino-groups of several other amino-acids and the imino-groups of proline and hydroxyproline react with *p*-diazobenzene sulphonic acid.

We have studied by spectrophotometric methods the reaction of diazotized sulphanilic acid with glycine, lysine, arginine and tryptophane. The compounds formed by glycine and lysine are characterized by absorption maxima at 363 mμ, and their extinction coefficients are of the same order as those shown by the azo derivatives of histidine and tyrosine[3]. The solutions are yellow, but the azo-amino compounds cannot be determined directly by colorimetric methods.

The usual initial procedure was to form the diazonium salt in acid solution by adding 1 ml. of 1 per cent solution of anhydrous sulphanilic acid in 10 per cent hydrochloric acid and 1 ml. of 5 per cent sodium nitrite solution to a 25 ml. flask containing an aliquot of the amino-acid solution not exceeding 10 ml., and after 30 minutes at room temperature to add 3 ml. of 20 per cent sodium carbonate solution and make up to volume with water.

The kinetics of the reactions of the amino-group are influenced by the *p*H attained, the optimum for lysine being at *c.* *p*H 9. The reactions are slower than the virtually 'instantaneous' coupling of histidine and tyrosine (which can, however, be analysed by indirect methods[4]), and the period elapsing between adding the alkali and diluting for measurement of the extinction was standardized at 30 minutes. The presence of ethanol in the system as in the method for histidine[5] reduces the extinctions considerably, and should be avoided. To minimize deamination the mixture of sulphanilic acid and nitrous acid can be diluted to about 10 ml. initially and the amino-acid solution added just before the alkali.

The extinctions at 363 mμ for the azo-derivatives of glycine and lysine both conform to Beer's law when referred to the initial amino-acid concentrations. The molecular extinction coefficient for the compound presumed to be *bis* (azobenzene sulphonic acid) glycine is *c.* 30,000. The lysine derivative gives similar values and the extinction remains constant when the initial molar ratio of lysine to sulphanilic acid exceeds $\frac{1}{2}$, suggesting that the ε-amino-group does not participate in the reaction. In the spectrum for the arginine derivative, the absorption maximum is displaced to 356 mμ and the extinction coefficient is lower than for glycine or lysine. The absorption spectra for the azo derivatives of histidine and tyrosine show only the bands characteristic of the ring azo derivatives[6], indicating that the diazonium salt reacts preferentially with the imidazole and phenolic groups of these amino-acids. Tryptophane[2] is reported to react at both the indole and amino-groups: our absorption curves support the view that the amino-group reacts, but only to a small extent.

The absorption spectra of the azo-derivatives of various intact proteins (casein, paracasein, α-casein, gelatin, pepsin, fibroin) and their acid hydrolysates have been examined. The extinctions at 363 mμ were found to increase with amino-nitrogen. A considerable amount of useful information about the constitution of a protein and the accessibility of its coupling groups can be obtained from a single absorption spectrum of this type, which is very much more sensitive than the ordinary ultra-violet absorption curve.

In applying the reaction to the determination of amino-groups in proteins and their degradation products, the main difficulty involves assessing the contribution of the imidazole, phenolic and imino-groups to the absorption at 363 mμ. However, in various possible applications of a comparative nature, such as following the course of hydrolysis, deamination, the action of a proteolytic enzyme or of peptide synthesis, such interference may not be relevant. The principal advantage appears to lie in the simplicity and rapidity with which the determinations can be made. The high values given by glycine in the Van Slyke manometric method of determining amino-nitrogen and the uncertainties in the interpretation of formol titrations emphasize the desirability of developing other methods of determining free amino-groups. A full account of these studies will be published elsewhere.

Half-value Periods for the Decay of Aluminium-26, Aluminium-25 and Nitrogen-13

THE decay of the positron-emitters aluminium-26, aluminium-25 and nitrogen-13 was measured using a nine-channel scaler, which recorded the counts received from a Geiger–Muller tube in nine successive equal periods. These periods were 2 sec. each for the two aluminium isotopes and 200 sec. each for the nitrogen isotope. The isotopes were produced by resonant capture of protons by magnesium-25, magnesium-24 and carbon-12, respectively. The proton beam was switched off when counting began, and the switching from one channel to the next was done by an electronic timer, accurate to one part in a thousand.

The half-value periods were calculated from these results using the rigorous treatment given by Peierls[1] and were as follows: aluminium-26, 6·68 ± 0·11 sec.; aluminium-25, 7·62 ± 0·13 sec.; and nitrogen-13, 602·9 ± 1·9 sec. The half-life measurement for nitrogen-13 is in fair agreement with those of 10·2 ± 0·1 min. and 10·1 min. obtained by Cook *et al.*[2] and Siegbahn and Slätis[3], respectively. Earlier published measurements ranging from 9·93 to 11·0 min. have been listed by Ward[4].

There has been some confusion previously in the measurement of the half-value periods of aluminium-26 and -25, due to the use of unseparated magnesium targets[5] and the fact that the two half-lives are of comparable value. In the present work separated magnesium-25 and -24 targets were used. The magnesium-24 targets were bombarded with protons of energy 418 keV. and the magnesium-25 targets with protons of energy 392 keV. Protons of these energies had previously been found to produce resonances on magnesium-24 and -25 isotopes respectively. It was also found that the yields from magnesium-24 for 392-keV. protons, and of magnesium-25 for 418-keV. protons, were each negligible.

Bradner and Gow[6] have observed half-lives of 6·3 and 7·3 sec. after bombarding separated magnesium-26 and -25 targets respectively with high-energy protons from a linear accelerator. These half-lives are ascribed to aluminium-26 and -25 produced by (p,n) reactions at this high energy, and are in each case somewhat lower than those obtained in the present work. The half-life of aluminium-26 has also been determined by Perlman and Friedlander[7], who obtained a value of 7·0 sec., and Allan and Wilkinson[8], who obtained a value of 7·0 ± 0·2 sec. Wäffler and Hirzel[9] obtained a value of 7·2 sec. and Katz and Cameron[10] one of 6·5 ± 0·1 sec.

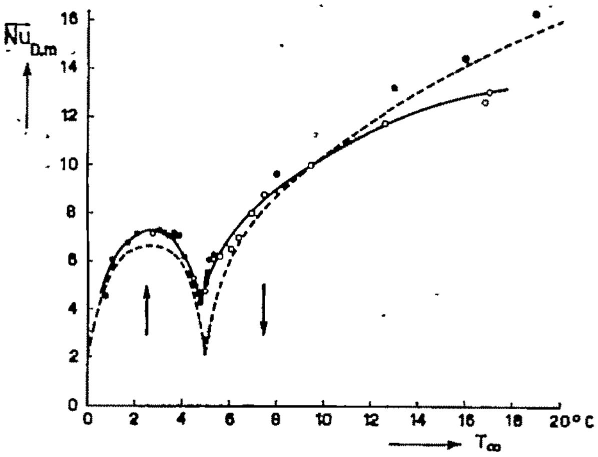
Heat Transfer from Water to Ice by Thermal Convection

HEAT transfer may be described by the coefficient α occurring in Newton's law of cooling, the other factors being the surface and the temperature difference. For bodies determined by one dimension, for example, a sphere of diameter D in an infinite fluid of conductivity λ, it is better to use the dimensionless Nusselt number $Nu = \alpha D/\lambda$.

By submerging a sphere of ice in water of temperature T_∞ (° C.) and studying the gradual decrease of its diameter or its change of weight in the course of time, we have found the experimental points, as shown in the graph. As the phenomenon is evidently related to the anomalous expansion of water, we take the coefficient of expansion to be a linear function of temperature $\beta = p + 2qT$, with $p = -64{\cdot}3 \times 10^{-6}$, $q = +8{\cdot}51 \times 10^{-6}$, and T being measured in deg. C. For the sake of brevity, we here omit a number of



Convective heat transfer water–ice, showing a minimum due to inversion of the convection current at 4·8° C. ○—○—, from observed diameter; ●—●—, from observed weight; - - - -, theoretical curve

minor refinements: the introduction of a term with T^2 in β, the influence of the excess liquid originating from the melting process, and the temperature dependence of Prandtl's number, Pr (the ratio of the kinematical viscosity ν to the heat diffusivity a of water).

The heat convection would normally be described by a law,

$$Nu = 0{\cdot}6\,(Pr.Gr)^{1/4},$$

the Grashof number Gr being given by $\beta g T_\infty D^3/\nu^2$. Because of the temperature dependence of β, we had, however, to recalculate the viscous flow in these circumstances, assuming in the usual way that this flow and the temperature gradient are restricted to a thin boundary layer, and applying the usual approximations to this layer. The result is that the same formulæ hold, provided we replace β in Gr by a more complicated expression, which reduces to

$$\beta' = p + 1{\cdot}51\, qT_\infty,$$

when the refinements are neglected. The factor 1·51 expresses the way in which the 'effective' or 'mean' expansion coefficient over the boundary layer is intermediate between the extreme values p and $p + 2qT_\infty$ occurring at its two sides.

From the values given, it is easily seen that β′ is zero for $T_\infty = 5°$ C. A slightly different and probably better approximation gives 4·8° C. At this temperature of the water a minimum of the heat transfer number Nu is to be expected, in good agreement with our experimental results. The value of the minimum is, of course, not really zero, as the resulting stagnation is irreconcilable with our assumption of a boundary layer. Indeed, the value of Nu could never fall below 2, the value for pure conduction by a stationary infinite fluid.

The direction of motion of the water in the boundary layer is opposite at the two sides of the inversion temperature 4·8° C., as indicated by the arrows in the accompanying figure. This has also been verified experimentally. A full account is to appear elsewhere[1].

Codegone[2] has observed a kindred phenomenon in water of temperature T_∞ accommodating itself to a hotter surrounding. His minimum occurs at $T_\infty = 4°$ as a consequence of the fact that only infinitesimal temperature differences occur in the water of his experiments, the outer wall of his vessel being heavily insulated. Another case of 'convective inversion' has been found by Powell[3] for humid air in contact with a wet-bulb thermometer.

An Interferometer for Simultaneous Observation of Concentration and Concentration Gradient in Liquid Columns

Several methods have been suggested for the observation of one-dimensional concentration and concentration gradients in liquids, a problem occurring in electrophoresis, ultracentrifuging and diffusion measurements; a bibliography has been given by H. Svensson[1]. In the methods for observing concentration directly, either Rayleigh or Fizeau interference fringes are used for plotting the optical path-length through the liquid; the methods for observing the gradient of the concentration use various modifications of the 'diagonal schlieren' system of Philpot; in all cases, complicated systems requiring a number of high-quality optical components are required.

In the method described here a simple and easily adjusted optical system plots both concentration and concentration gradient simultaneously as interference fringes superimposed on an image of the cell containing the liquid.

Referring to the plan view in Fig. 1, S is a monochromatic source of light near the focus F of a collimator K; C is a double cell containing liquid with varying concentration in one compartment (A) and homogeneous liquid in the other (B); M is a plane mirror, W a Wollaston double-image prism of doubling angle φ, and P a 'Polaroid' screen with its principal directions at 45° to those of W.

The divergent wave-front from S is split by P and W into two coherent plane-polarized wave-fronts; these are indicated at s_1 and s_2 after passing through K. Corresponding points on s_1 and s_2 are separated laterally by a distance $\delta \approx \varphi . KF$ and s_1 and s_2 are inclined to each other at an angle α which depends on the distance of W from F. The wave-fronts s_1 and s_2 return from M and are recombined by W and P, but corresponding rays have traversed different parts of C so that, on viewing from S' (which is the image of S), two horizontally separated images of C, 1 and 2 are seen.

The wave-fronts s_1 and s_2, being coherent, will form interference fringes which are loci on which the

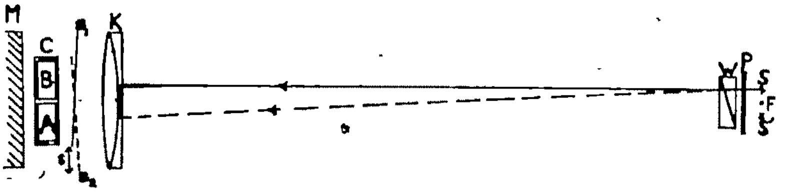

Fig. 1

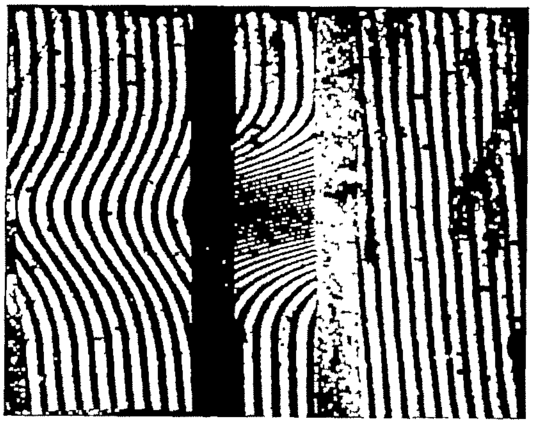

A_1–A_2 B_1–A_2 B_1–B_2

Fig. 2

difference between optical path-lengths along corresponding rays of s_1 and s_2 is constant. The arrangement of Wollaston prism and polarizer is essentially the same as that used by Lenouvel[2] as a wave-front shearing interferometer for determining the aberrations of optical instruments.

If the doubling angle φ is suitable, the two images of the cell will partly overlap. Let x and y be horizontal and vertical co-ordinates in the cell, and let $V(y)$ be the optical path through compartment A at height y; then, in the region where image A_2 overlaps image B_1, the bright fringes satisfy the equations

$$V(y) + \alpha x = \tfrac{1}{2}k\lambda, \quad (k = 0, \pm 1, \pm 2, \ldots) \qquad (1)$$

Thus the x-displacement of any fringe at height y is a linear function of the refractive index at y, so that the fringes in the A_2–B_1 region map the concentration in the cell.

If, in addition, W and P are turned through a small angle about the optical axis, the lateral separation δ between s_1 and s_2 will have a small vertical component, say, ε; then, in the region where A_1 overlaps A_2, the equations of the fringes will be

$$V(y+\varepsilon) - V(y) + \alpha x = \tfrac{1}{2}k\lambda, \ (k = 0, \pm 1, \pm 2, \ldots),$$

which can be written in the form

$$\alpha x = -\varepsilon\left\{\frac{V(y+\varepsilon) - V(y)}{\varepsilon}\right\} + \tfrac{1}{2}k\lambda. \qquad (2)$$

Thus, the x-displacement of any fringe is, for a small enough value of ε, a linear function of the gradient of the refractive index, so that the fringes in the A_1–A_2 region map the concentration gradient.

In both cases the constants of the linear relations in question are easily determined; the horizontal scale of the integral and gradient patterns can be varied together by moving W and P along the axis, while the scale of the gradient pattern alone can be varied by rotating W and P.

The fringe system can be photographed by placing a camera behind S'. The photographs in Fig. 2 show fringes obtained from a diffusion boundary; the straight fringes in the B_1–B_2 region indicate the direction of the base-line from which the x-displacement should be measured. The cell used was 1 cm. thick and the wave-length was 0·5461 μ, so that a displacement of one fringe corresponds to a refractive index increment of 0·000027.

The two images of S are recombined at S' in such a way that the fringe systems formed by the different points of S all coincide, so that no restriction on the size of the source is needed to obtain maximum fringe contrast. Such a restriction is needed only to ensure that the rays do not traverse the concentration gradient at too great an angle to the horizontal; the maximum permissible angle is obviously of the order of magnitude of h/t, where h is the vertical separation between successive fringes in the region of steepest gradient and t is the cell thickness. For work where the last condition is not important, the collimator and plane mirror could be replaced by a concave spherical mirror; also, modifications to suit different cell designs could easily be devised.

Thanks are due to Mr. E. G. Menage, of this Section, who made the cell and the Wollaston prism.

Thin Metallic Films for Anti-Reflexion Coatings on Dielectric–Air Interfaces

In the course of some experiments with thin rhodium films, I noticed that the intensity of light reflected from a rhodiumized glass–air interface is much less than that reflected from the same interface when used in the air–glass sense. Sheared wave-front interferometric study of the edge of such a film indicated that this may be primarily due to a half-wave phase shift which can be seen at the glass–air boundary, but not when the same boundary is air–glass, the out-of-phase condition reducing the reflective intensity.

When the rhodium film had transmission factors exceeding 50 per cent the effect became so marked that the rhodiumized glass–air interface had reflexion factors markedly less than the uncoated portions of the same surface. By examining a continuously graduated coating it was established that the reflexion intensity is virtually zero when the transmission factor of the rhodium film is 70 per cent. This applies to glass having a refractive index about 1·52.

The reflected intensity was so low that microscopic examination of the surface by normal, bright-field vertical illumination resulted in a very striking dark-field image, dielectric particles and chemical film patches deposited on the surface appearing brightly illuminated against a black background. The chemical film patches and crystals produced interference colours markedly resembling those seen when viewing birefringent crystals in transmitted light between crossed nicols.

Although the transmitted light absorption and the uni-directional condition both impose severe limitations, the method may prove useful where all that is required is to prevent internal reflexions. It may be possible to improve the transmitted light intensity by using metals other than rhodium, though the latter seems the obvious choice for the microscope arrangement described above.

Effect of Anomalous Attenuation in a Linear Accelerator

IN a recent communication[1], the performance of a travelling-wave linear accelerator has been given. It was shown that, due to the importance of higher terms in the expansion representing the power flow in the accelerator guide, the series impedance is lower than had been previously assumed. This, of course, leads to a reduction in the energy of the accelerator. The series impedance for the guide in question (2 cm. pitch, $a/\lambda = 0 \cdot 168$ and phase velocity approximately equal to light velocity) has been determined both theoretically and experimentally, and a value of 3·5 megohms/cm.[2] obtained. From this value and experimentally determined data on the position of electron bunching, the energy expected from the accelerator may be calculated for various loading conditions. Such values are shown compared with the measured performance of the accelerator in Fig. 1, and it will be noted that, although agreement at light loading is good, serious discrepancy occurs at higher loading. The discrepancy is attributed to an anomalous attenuation which has been found to occur in the accelerator over a certain range of power flux.

Although measurements of attenuation of the three-metre length of guide and associated components indicate a value of 2·5 db. for all power-levels in the absence of magnetic focusing field, the application of such fields is found to have a considerable effect. In the presence of focusing fields the attenuation, although still of the order of 2·5 db. for power fluxes of a few milliwatts and several megawatts, exhibits a variation with power in an intermediate range. In this particular case, an attenuation greater than 12 db. has been noted for an input power of 250 kW., and as power is increased attenuation falls, approaching 2·5 db. for an input of 3 MW. The effect is apparently not dependent on the gas pressure in the guide, provided that this is reasonably low. It would therefore appear to be additional to the radio-frequency absorption by gas noted by Harvie and Mullett[3] and which has also been observed in the present equipment.

At light loading the power-level in the guide is such that anomalous attenuation may be expected to have little effect. When, however, the loading is increased, the power flux is considerably reduced and anomalous attenuation may be expected to affect performance. The mechanism causing the increase in attenuation is not fully understood, and it is therefore impossible to make an accurate allowance for the effect. If, however, it is assumed that the criterion which determines the value of the anomalous attenuation is the mean of the input and output power fluxes, the calculated performance figures may then be modified. Such modified results are shown in the graph and, clearly, improvement in agreement with the measured performance is obtained at the higher loadings.

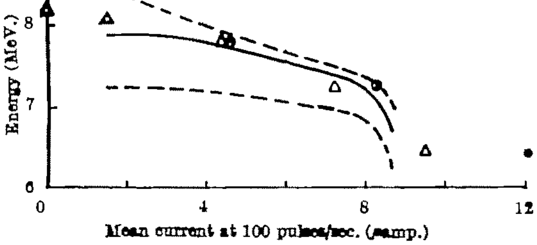

Fig. 1. Comparison of measured and calculated energies: ——, measured energy of peak of spectrum; – – – –, approximate limits of spectrum. Points shown as ○ are calculated neglecting anomalous alternation, and △ making an allowance for anomalous attenuation

A similar increase of attenuation has been noted[3,4] in a dielectric-loaded guide by the Linear Accelerator Group at Malvern of the Atomic Energy Research Establishment, and a qualitative explanation of the effect has been suggested in terms of secondary emission and multi-pactor effect inside the corrugations of the guide.

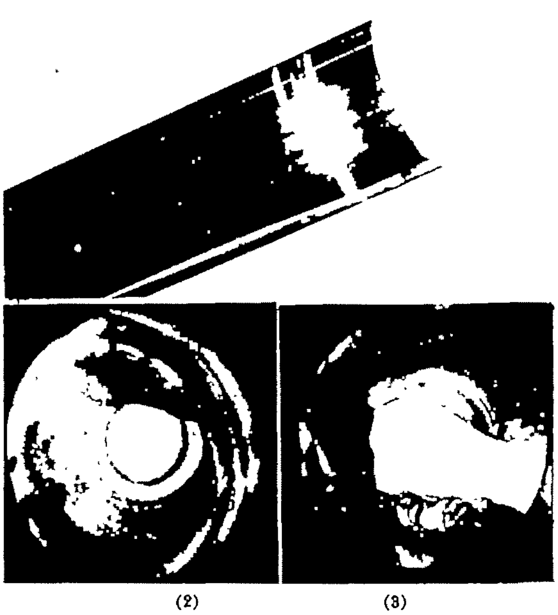
Transverse Cracks in Glass Rod

IN the course of work on crack propagation in brittle fracture, we have been breaking glass rod in tension by the Bridgman[1] technique of applying radial fluid pressure. A few specimens, cut from one 9-mm. diameter 'Hysil' glass rod, contained after fracture transverse cracks which had not been propagated completely across the section, as shown in Fig. 1. The diameter and thickness of the large crack in this specimen can be estimated from the end view (Fig. 2); this was taken with mercury light, and since it shows four interference fringes the crack was about 10,000 A. thick in the centre.

(1)



(2) (3)

(1) Cracks in glass rod (×2½), (2) end view of rod (×3½) (3) fracture surface of crack in (2) (×3½)

Although these cracks appear to be completely enclosed, most of them could be traced to the surface on one side. The cracks could be propagated across the specimen by a shock load, and the resulting fracture surface (Fig. 3) revealed the flat (white) specular region of the original crack extending on one side to the edge, surrounded by the complex array of steps and fissures of the subsequent fracture. At higher magnification, under the opaque stop microscope[2], it could be seen that the original crack started at the surface and spread progressively into the centre of the rod.

The nature of these cracks suggests that the rod contained axial internal stresses which were tensile in the core and compressive in the periphery. This stress system could well arise during cooling, and accounts for the existence of completely internal cracks and for the enclosed appearance of the remainder when the load is removed.

Magnetic Study of Amethyst

AMETHYST (a well-known variety of quartz) has a rich violet colour, the origin of which has been discussed by several workers. Tutton[1] states that the twinning of right-handed and left-handed quartz may be the probable cause. Holden[2] has suggested that an impurity like iron oxide imparts the colour. An inorganic dye, the physical state of aggregation of which changes on heating, has also been mentioned as another possibility. It was felt that a magnetic study of quartz and amethyst may throw some light on this problem.

Two specimens of amethyst were available. One of them had a uniform violet colour. Coloured and colourless crystals had grown on the same cluster. The specific gravity and the mean specific susceptibility of quartz were 2·654 and − 0·40 respectively (all susceptibility values are given in 10^{-6} unit). For amethyst, these values were 2·656 and − 0·33. Crystals in the other group had three different portions. One was colourless, another had a light uniform colour and the third was dark and not uniform. Samples from these portions gave mean susceptibility − 0·33 for the first, − 0·112 for the second and values ranging from + 0·20 to + 0·53 for the third. There was no evidence of any free ferromagnetic impurity in any of the specimens.

Amethyst loses its colour when it is heated to about 260° C. A few carefully chosen crystals were baked at 430° C. for about two hours. On redetermining the susceptibility, the diamagnetic value was always found to show a rise. The increased value was, however, still far below the diamagnetic value for pure quartz. In a representative case, the values before and after heating were − 0·200 and − 0·216 respectively.

These results show that the tinctorial agent is paramagnetic. The possibility of manganese is excluded, since crystals which do not show any trace of manganese are known to be highly coloured[3]. The magnetic evidence supports the view that the colour is due to ferric iron, existing as ferric hydroxide or a mixture of ferric oxide and ferric hydroxide. On heating the crystal, the stable ferrous oxide appears to be formed. The conversion of the ferric ion into the ferrous ion is accompanied by a slight diminution in the paramagnetic component.

Chemical tests showed that while moderately coloured crystals contained 0·21 per cent of ferric iron, strongly coloured specimens gave 0·31 per cent. These quantities are just of the right order of magnitude to account completely for the paramagnetism of the corresponding amethyst crystals.

The magnetic anisotropy of quartz and amethyst were studied by Krishnan's critical torsion method[4]. For two specimens of quartz, $\chi_{\perp} - \chi_{\parallel}$ (the axis of reference being the rhombohedral axis) was found to be 0·113 and 0·130. The light-coloured crystals showed an anisotropy of 0·042, whereas for strongly coloured specimens it was 0·0114. These results show that the anisotropy is reduced by the colouring matter, $\chi_{\parallel}$ being more influenced than $\chi_{\perp}$.

Details of this work will be published elsewhere.

New Erythrean Fishes from the Mediterranean Coast of Israel

SINCE the opening of the Suez Canal, Erythrean fishes have penetrated to the region of the eastern Mediterranean. This penetration is still taking place and the results can be seen in: (*a*) appearance of new Erythrean species in the eastern part of the Mediterranean; (*b*) the spreading of Erythrean species, already established in the eastern Mediterranean close to the Suez Canal, to new areas (a movement following the coast of Israel, Syria, Turkey and Rhodes); (*c*) the increased abundance of the invading species in areas where they were formerly scarce.

In order to follow all the changes, it is necessary to carry out frequent faunistic observations in this part of the Mediterranean. Unfortunately, the eastern Mediterranean has been little investigated from an ichthyological point of view, and in many cases the reports on the changes in fish distribution have been issued after great delay.

The fishes determined and listed here were caught between October 1951 and June 1952. The collection of the Sea Fisheries Research Station, however, contains also specimens caught during previous years, such as *Sphyraena obtusata*, *Callionymus* cf. *brunneus* (see below) and *Apogon duops* from the year 1947; Lissner[1] noted *Dussumieria* sp., and G. Haas and H. Steinitz[2] reported *Platycephalus* sp.

Kosswig[3] gives an extensive survey on the infiltration of Erythrean species to the Mediterranean. His paper contains a list of twenty-four species reported by different authors; but he pointed out that the presence of some species was not confirmed and the determinations of taxonomically more difficult genera (*Caranx*, *Serranus*) might be wrong. Hence he limited the number of definitely established Erythrean species in the Mediterranean to fifteen. Haas and Steinitz[2] listed ten Erythrean species from the Mediterranean coast of Palestine. Several of them are now very common: *Mulloides auriflamma* is caught by trawl in considerable quantities and is of commercial value; *Siganus rivulatus* and *Stephanolepis ocheticus* are among common fishes met with along the shores; *Hepsetia pinguis* is the most abundant among Atherine fishes of this coast.

To the list of Red Sea fishes already mentioned from the Mediterranean but not previously reported from the Israel coast should be added: (1) *Tetrodon spadiceus* (Rich.); (2) *Upeneus* sp.

Besides these fishes, eight Indo-Pacific species were also determined, which so far as it is known have not yet been reported from the Mediterranean. Part of them, however (the first four in the list below), have been observed in the Suez Canal[4-7]. These fish, found along the Israel coast-line, have been identified as follows: (1) *Dussumieria prouctissima* Chab., common along the shores and often caught by trawl and purse seine; (2) *Sphyraena obtusata* C.V., caught in considerable quantities by trawl and ring net; (3) *Caranx djeddaba* (Forsk.), kindly determined by J. T. Nichols of the American Museum of Natural History; (4) *Apogon thurstoni* Day, appears often in Haifa Bay; (5) *Istiophorus gladius* (Brouss.), a young specimen 356 mm. in total length; (6) *Callionymus* cf. *brunneus* Fowler, common bottom-fish along the shores. The addition of 'cf.' indicates some systematical deviation from Fowler's description; (7) *Saurida grandisquamis* Gthr., caught occasionally in Haifa Bay during winter months; (8) *Platycephalus indicus* (L.), rare.

Measurement of Colonization and Survival of Soil *Fusaria* in Detached Plant Tissue

THE colonization in soil of detached host tissue by soil-inhabiting parasitic fungi was demonstrated by Sadasivan[1] with *Fusarium culmorum*. Recently, this technique has been utilized by several University of Madras research workers in studies to determine the effect of micro-elements on the colonization and survival of *Fusaria* in cotton and gram (*Cajanus cajan*) roots[2-4]. Generally, they found that zinc, aluminium, boron, lithium, manganese and cobalt at soil concentrations from 100 to 400 p.p.m. retarded *Fusarium* colonization and survival.

Investigations on flood-fallowing for the eradication of *F. oxysporum* f. *cubense* are seeking to determine some of the factors involved in the survival or non-survival of this fungus in both submerged and non-submerged soils[5,6]. The root-colonization technique is a valuable tool in these studies although quantitatively this method is not sufficiently accurate. Previously, quantitative data have been obtained by culturing on agar approximately 25 root pieces per treatment to determine percentage colonized, that is, yielding *Fusarium* colonies, or similarly, percentage fungus survival in previously colonized roots subjected to treatment[7].

In the case of fleshy roots, such as bananas, decay is rapid and in a period of 2–3 months only the tubular parchment-like periderm and woody stele remain. Culturing of these decayed root pieces to determine percentage colonization or survival gives erratic results even when large numbers are used. This lack of consistency is attributed in part to the rapid development of bacteria and saprophytic fungi on the agar plates. Some of the fungi, which are rapidly growing spreaders, have been observed to inhibit or obscure developing *Fusarium* colonies. Also, the extent of colonization cannot be accurately determined unless numerous small pieces of the root are cultured separately.

In studies on the effect of soil moisture on *Fusarium* survival in colonized banana roots, it was observed that this fungus developed rapidly and abundantly on agar plates after decayed colonized roots were finely cut in a Waring blendor and diluted with water[8]. The Waring blendor–dilution technique was developed further[8] and recent unpublished data indicate it to be amenable to an improved quantitative analysis of *Fusarium* growth and survival in colonized roots. Fragmentation of mycelium using this technique results in a much higher colony count than would be obtained by other methods. Thus, this method is particularly valuable in determining minute areas of survival that are rapidly overgrown and inhibited from development on culture media by soil saprophytes including other *Fusarium* spp. Of course, mycelial fragmentation tends to indicate a higher level of survival than may actually exist. Nevertheless, in diseases such as the *Fusarium* wilts, any level of fungus survival indicated is of value in predicting the subsequent behaviour of susceptible or partially resistant varieties.

The Waring blendor–dilution technique is being used in studies to determine the effect of various compounds on colonization and survival of soil *Fusaria* in detached plant tissue. Using this method of measuring colonization and survival of *F. oxysporum* f. *cubense* in banana roots, the micro-elements zinc, boron and manganese at concentrations of 100 and 200 p.p.m. have exerted no significant effect. Survival in colonized roots has occurred even under treatments that eradicated the fungus from the surrounding soil. These treatments included submerging the soil and roots for three months under two inches of water with and without sodium nitrate, and saturating the soil with aqueous solutions containing 400 p.p.m. of various fungicides. Thus far, cyanamid at 2,500 lb. per acre and 1 per cent formaldehyde drench have been effective in drastically reducing *Fusarium* survival in colonized roots in the laboratory.

A detailed report of these studies will be made elsewhere.

FORTHCOMING EVENTS

Monday, September 7—Friday, September 11

Institution of Chemical Engineers and Chemical Engineering Group (Society of Chemical Industry) (at Olympia, London, W.14).—Chemical Engineering Conference.

Tuesday, September 8—Thursday, September 10

Faraday Society (in the Department of Chemistry, Leeds University, Leeds).—General Discussion on Dyeing and Tanning.

Wednesday, September 9

Institute of Petroleum (at Manson House, 26 Portland Place, London, W 1), at 5.30 p.m.—Mr. F. W. B. Porter: "Autofining".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturer in Agricultural Chemistry at the University College of the Gold Coast—The Secretary, Inter-University Council for Higher Education in the Colonies, 1 Gordon Square, London, W.C.1 (September 10).

Lecturer in Genetics in the Department of Botany at the University College of the Gold Coast—Secretary, Inter-University Council for Higher Education in the Colonies, 1 Gordon Square, London, W.C.1 (September 10).

Senior Assistant Engineer (with honours degree in electrical or mechanical engineering, and preferably with research experience on steam turbine plant) at the British Electricity Authority Research Laboratories, Leatherhead, to carry out testing, development and research work in connexion with electricity generation—The Director of Establishments, British Electricity Authority, Winsley Street, London, W.1, quoting N/412 (September 12).

Electrical Engineer (with degree or diploma in electrical engineering or equivalent qualification, and preferably with experience of light electrical engineering, including electronics) at the Technical and Scientific Register—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting D.334/53A (September 14).

Lecturer (with honours degree in botany, zoology or horticulture) in the Department of Biology—The Principal, Wigan and District Mining and Technical College, Wigan (September 14).

Research Assistant in the Department of Geography—The Secretary, University College, Gower Street, London, W.C.1 (September 19).

Senior and Junior Research Fellow in Anthropology, and a Senior Research Fellow in Psychology in the East African Institute of Social Research, Makerere College—The Secretary, Inter-University Council for Higher Education in the Colonies, 1 Gordon Square, London, W.C.1 (September 19).

Assistant Lecturer in Philosophy—The Secretary, The University, Belfast (September 21)

Senior Lecturer in Chemistry and a Lecturer in Science at Fourah Bay College, Sierra Leone—The Secretary, Advisory Committee on Colonial Colleges, 15 Victoria Street, London, S.W.1 (September 21)

Director (with experience in timber technology, and in the utilisation of tropical timbers) of a Forest Products Research Laboratory in Burma, to plan and develop the laboratory as regards buildings, equipment and organisation—The Burmese Embassy, 19A Charles Street, London, W.1 (September 22).

Assistant Lecturer (with honours degree in agricultural chemistry or chemistry) in Agricultural Chemistry (Dairy Chemistry)—The Registrar, The University, Reading (September 26).

Research Officer (with university honours degree with physics as a major subject or equivalent qualification) in the Division of Metrology, Commonwealth Scientific and Industrial Research Organization, Chippendale, N.S.W., Australia, to carry out research in interferometry (optical and microwave) with particular reference to the measurement of length and associated quantities—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting 750/32 (September 26).

McRobert Research Fellowship to undertake research relating to any disease that is generally regarded as malignant or incurable in any one of the following fields selected by the candidate and approved by the University: Bacteriology, Biology, Chemistry, Chemotherapy, Clinical Science, Endocrinology, Pathology or Physics—The Secretary, The University, Aberdeen (September 30).

Research Assistant in Metallurgy—The Registrar, University, Manchester 13 (October 1).

Chair of Education in the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (October 15).

Assistant Lecturer, Grade "B", in Mathematics, at the Wolverhampton and Staffordshire Technical College—Clerk to the Joint Education Committee, Education Offices, North Street, Wolverhampton.

Chemist-Assayer (with honours degree in chemistry and (a) Certificate from University of having reached a good standard in practical inorganic chemistry, and a two-year course of postgraduate training at the Imperial College of Science and Technology; or (b) at least two years postgraduate experience in silicate analysis and assaying) in the Gold Coast—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting CDE.105/13/06.

Electrical Engineers, (a) Scientific Officer class (with first- or second-class honours degree in electrical engineering or equivalent) or (b) Experimental Officer class (with H.S.C., science, or equivalent) at Ministry of Supply Experimental Establishments at Malvern, Farnborough and Sevenoaks, for research, development or design in telecommunications, radar, electronics, instrumentation or light electrical measurements—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting D.232/53A.

Engineer (A.M.I.C.E., B.E. or M.E., or with exempting qualifications) with the Ministry of Supply, Hayes, to control inspection of all types of electronic equipment—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting D.327/53A.

Engineers (A.M.I.Mech.E. or A.M.I.E.E., or equivalent) or Physicists (with honours degree in physics or chemical engineering and/or A.Inst.P., A.M.I.Chem.E., or equivalent) in the Division of Atomic Energy (Production), at Risley and Capenhurst, to undertake the design, adaptation and development of (a) instruments, including electro-chemical types for measurement of temperatures, pressures, pH flow and radioactivity, and (b) equipment for analysing gases and liquids—Ministry of Supply, Division of Atomic Energy (Production), Risley, Warrington, Lancs, quoting 492.

Professor of Geography—Dr. A. A. Duri, Dean, College of Arts and Science, Baghdad, Iraq.

Research Fellows in Geophysics, including petrology and crystal and high pressure physics—The Registrar, Australian National University, Box 4, G.P.O., Canberra, A.C.T., Australia.

Supervisors (with a diploma or degree from a recognised school of metalliferous mining, and at least five years experience of alluvial prospecting) in the Mines Department, Nigeria—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting CDE.90/14/04.

Timber Research Officer (with honours degree in engineering) in the Department of Forestry, Federation of Malaya, to take charge of new timber research laboratory at Kepong, where investigations are carried out on Malayan timbers—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting CDE.61/60/01

THE EDUCATION SYSTEM IN GREAT BRITAIN

AN impartial observer is unlikely to claim that the Government has as yet distinguished itself in the field of education, though perhaps the recent introduction of the Minister of Education into the Cabinet heralds a change. For the past, hopes entertained in the field of higher technological education have not materialized, though both major political parties are committed to the establishment of, at any rate, one major technological institution of university rank. Of a policy for technical education there has been no sign, and a speech of the Prime Minister's, if not his personal intervention, redeemed a situation in which alarm over the future of adult education had been caused. A recent report on the schools by the Select Committee on Estimates has been used for attacking the Government; but the shortcomings revealed by that report are the responsibility of successive governments and must be shared equally by both parties. The real burden of that report is one equally implied by the subsequent report of the University Grants Committee, and is a challenge to realistic thinking which both political parties must heed.

The report in question, the eighth from the Select Committee on Estimates for the Session 1952–53*, is based on the Committee's examination of the expenditure on schools proposed in the estimates for public education in England, Wales and Scotland for 1953–54 in the light of the intention of the Education Acts of 1944 and 1946. At every point the Committee was confronted with overcrowding, lack of schools, heavy transport costs, a shortage of teachers and often rapidly deteriorating and even dangerous school buildings. It points out that the high birth-rate between 1944 and 1948 has swollen the population in primary schools beyond what may be regarded as an average annual expectation. This increased number of scholars will soon be entering secondary schools which, with their requirement for smaller classes, will experience even greater difficulties than the primary schools have done. It is unlikely to affect university entry until about 1960. Besides this, the general shortage of materials and labour has proved far worse over a longer period than was foreseen in 1945, and the impact of the defence programme has been another adverse factor.

In a reply to the Committee's criticisms, published on July 17, the Ministry of Education does not agree that competing demands upon materials and labour made by the housing programme are a main cause of any difficulty in the school building programme keeping pace with the housing programme, or even that the cuts in capital expenditure made in 1951 and the subsequent three months moratorium had an adverse effect on the school building programme. The Ministry also refuses to accept the Select Committee's conclusion that insufficient care was taken in estimating the number of school places which must be provided, and affirms that it is the Ministry's policy to build new schools to reduce the size of classes, or to eliminate the need for makeshift accommodation. The policy of the present Ministry, and of its Labour predecessor, it is stated, has been based on the fact that building resources were not adequate both to meet these needs and to provide school places for the growing number of children and for the children moving to new areas.

---

* Eighth Report from the Select Committee on Estimates, together with the Minutes of Evidence taken before Sub-Committee B and Appendices. Session 1952–1953. Schools. Pp. xxii+233. (London: H.M. Stationery Office, 1953.) 9s. net.

The reply does not deny that the condition into which many of the older schools in Great Britain have fallen is the worst feature of all educational buildings, or that the Ministry has assumed that the buildings available at the end of the War must be deemed to be acceptable for the next decade or more. The Ministry's reply to the criticisms of the Select Committee is clever rather than convincing. It is concerned rather to defend and to save the face of the Ministry and in doing so, quite independently and irrespective of the political nature of successive Governments responsible for the same policy, only emphasizes the gravamen of the main charge of the Select Committee and which it studiously avoids.

That charge, not indeed explicitly formulated, is that in respect of the educational programme to which both political parties have committed themselves under the Acts of 1944 and 1946, the resources allotted to education have been quite inadequate. The Ministry of Education has been attempting to carry out an impossible task. Either it must be given the resources that it requires for the task or the educational aims and programme should be adjusted in accordance with whatever allocation of resources can be made in consideration of other national needs.

If the facts disclosed by the Select Committee's report make nonsense of the Ministry of Education's disclaimer for estimating requirements and rebuke both Governments alike responsible for educational policy since the War for lack of realism, they no less make nonsense of the large proposals for the reform of secondary education advanced in the Labour Party's statement, "Challenge to Britain". Whatever the merits of the abolition of 'the eleven-plus' examination, the proposal to replace existing grammar schools and public schools by a system of new comprehensive secondary schools involves an even larger building programme at a time when the increase in the school population is likely to make it even more difficult to secure the smaller classes, if not the larger number of teachers, upon which success will largely depend. There may well be much to be said for the proposals for comprehensive secondary schools, but their merits are as yet unproved. The Estimates Committee's report shows clearly that the prospect of achieving the conditions essential for the success of any such drastic change are for the present remote on purely practical grounds.

This argument is supported by an analysis of the cost of social services during 1938–52 made by Political and Economic Planning in a recent broadsheet (No. 354, June 15, 1953). Whereas in 1938–39 expenditure on education amounted to £111·8 millions out of a total expenditure on social services of the United Kingdom of £527·4 millions, in 1951–52 it was £328·2 millions out of £2,011 millions. As a percentage of the national income it had only increased from 2·0 to 2·2 and now stood fourth to the social security services (including social insurance, assistance, war pensions, family allowances and poor relief), the second place (3·3 per cent compared with 1·3 per cent in 1938–39) having been taken by health, hospital and domiciliary services, while food subsidies accounted for 2·3 per cent. Expenditure on education per child under fifteen had risen from £10 17*s.* to £28 13*s.*, while between 1938 and 1951 the number of children in the 5–14 age-groups attending grant-aided schools rose by about 10 per cent.

That is, of course, not to deny the practicability or indeed the desirability of limited and careful experiment in this direction, so that when it is possible to allocate increased and adequate resources to the school building programme there may be available some practical evidence of their value and potentialities as against the proved value of the grammar schools and the public school system. A decision might then be possible not on the grounds of political or social theory but on more substantial grounds of educational experience. New needs, as Rashdall reminded us in his great work on the universities, must be met by new machinery, and universities are not the only educational institutions which must undergo perpetual modification in the future as they have undergone it in the past. Here also it is wise, as in wider fields of social, political and religious organization, so far as possible to preserve historical continuity, and to remember Zinsser's affirmation that no democracy can maintain itself for any length of time without building up an aristocracy of ability and talent to protect it from deterioration and eventual chaos.

It would be unfortunate, indeed, if the Ministry of Education's concern to save its own face led it to neglect to implement the several very sensible recommendations of the Select Committee for improving the situation. They are minor rather than fundamental, though they should encourage a more realistic attitude and some attempt to bring educational aims and policy more into line with the resources which the Government is prepared to allocate. More fundamental and critical thought, however, is demanded as well as more sincerity, and it is as a contribution to such thought that a further book on education by Dr. J. B. Conant is to be welcomed*.

Dr. Conant believes with Mill that the worth of a State, in the long run, is the worth of the individuals composing it and that a State which dwarfs its men, in order that they may be more docile instruments in its hands even for beneficial purposes, will find that with small men no really great thing can be accomplished. For him the issue between liberty and totalitarianism depends on whether democracy, as the term is commonly understood in the Western world, can throw up not merely an *élite* but ordinary citizens capable of meeting the intellectual and moral demands which the functioning of a democratic system makes. The answer to this in turn depends largely on the nature of the educational system. Dr. Conant's book is essentially a tract for the times in which the axiom that "liberty can never be safe but in the hands of the people themselves, and that, too, of the people with a certain degree of instruction" is examined in the context of what degree of instruction it implies should be provided in the context of to-day.

---

* Education and Liberty: the Role of the Schools in a Modern Democracy. By James Bryant Conant. Pp. xv+168. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1953.) 20*s.* net.

But Dr. Conant's examination is more limited than his title or sub-title implies. The Jeffersonian axiom just quoted is taken as text for three lectures given at the University of Virginia which were not merely addressed to an American audience but were concerned with the role of the schools in a particular democracy—the United States. In the first, under the title the Anglo-Saxon tradition, a comparison is given of the present status of secondary education in the United Kingdom, Australia, New Zealand and the United States. This is followed by an account of the American institution, the liberal arts college with its four-years course, and of its influence on secondary education in the United States. This includes some account for the American citizen of the British university system and its relation to the schools, while the third lecture, or chapter, outlines the problems in this field which immediately confront the United States, and details Dr. Conant's own proposals to meet a situation in which a fifty per cent increase in the number of adolescents is expected in 1960.

Dr. Conant's book is accordingly of less general interest than might at first appear. Because he could assume on the part of his American audience or reader a knowledge of conditions in the United States which will not normally be shared by a British reader, for the latter his exposition will not have quite the same sharpness of meaning as for an American reader. In this book he is likely to be more successful in explaining the British system and practice to an American reader than the United States system to a British reader. Moreover, Dr. Conant regards education as a social process, related in each century to the current political scene, to social history and national ideals. The social behaviour characteristic of a people is more significant in determining the nature of the schools than the acceptance of any particular philosophy of education. Nor does Dr. Conant believe that educational practices are an exportable commodity.

Here can be seen the real value of Dr. Conant's book for those outside the United States. Firmly rejecting the doctrinaire approach which has marred much current discussion, he insists that if the educational experience in one country is to be any help to another, a determined effort must be made to think out the situation objectively and to take account of contrasting social outlook and experience before attempting to apply either system or practice. It is a challenge to thought which is the more topical and stimulating in view of the controversy over the comprehensive high school in Great Britain, and the proposals already mooted for jettisoning both the public school and the grammar school in favour of the unproved and still hypothetical advantage of the comprehensive school.

Dr. Conant himself is a convinced believer in the comprehensive high school for America, partly because he believes it favours social coherence and partly because he approves of vocational specialization starting late. But he is concerned that such a system does accept lower standards for the sake of a more widely diffused education, and still more is he concerned at its failure to provide adequate opportunity for the gifted. He recognizes the need for more attention to this question of the aristocracy of talent and for assuring diversity in education, and his warning that educational *practices* are not exportable only emphasizes the value of the interchange of thought.

Dr. Conant's book is not profound; but although its straightforward account of different educational systems is clearer to an American than to an English reader, the latter will find the book both topical and suggestive. It gives clear warning of the dangers of a doctrinaire approach to educational problems and especially of allowing such an approach to determine practice without regard to the whole social and educational context. Dr. Conant, moreover, does not believe in abandoning or disturbing established educational systems except for very clearly demonstrated reasons. For all his advocacy of the American high school, he would be the first to warn us that before attempting to import such a system or practice, we should be quite clear first as to what fresh contribution to education that system had made in the United States and what values it had brought to politics, to culture, entertainment or social life that would justify abandonment of our own system. Even if such a change were justified, Dr. Conant, who believes also in experiment and in change, would remind us that what Bacon wrote of innovations was never more true than of innovation in education: "It were good, therefore, that men in their Innovations would follow the example of Time itself, which indeed innovateth greatly, but quietly, and by degrees scarce to be perceived".

THE WORKERS' EDUCATIONAL ASSOCIATION

The Workers' Educational Association

The First Fifty Years. By Mary Stocks. Pp. 157. (London: George Allen and Unwin, Ltd., 1953.) 12*s*. 6*d*. net.

THE history of any organization which is celebrating a special occasion is often no more than a dull catalogue of events which has little interest except for those few people who were in some way connected with those events. One might be forgiven, therefore, if one confessed that, after reading Mary Stocks's apologetic preface to this book, one anticipated a wearisome chronicle which had to be read out of a sense of loyalty to the unique efforts of the Workers' Educational Association in adult education.

Never were fears so groundless. Mrs. Stocks has written a remarkably moving story which is full of fascination. The history of the Workers' Educational

Association is so skilfully woven with the social history of the past fifty years that it would have done no discredit to its publishers if the book had also been advertised as a history of the working-class movement in the past half-century.

The key to the book lies in the first chapter. In 1903 the Workers' Educational Association was born; otherwise the year had little to commend it. But Mary Stocks examines the stirrings and movements of the time and prepares the canvas on which she later paints her magnificent portrait of the Workers' Educational Association. In later chapters, her sense of history enables her to relate the growth of this unique adult education movement to the personal, social and economic forces which moulded it. This fine feel for the event of the moment is never better seen than in her account of Mansbridge's almost fatal illness or of the activities of the Workers' Educational Association after the outbreak of the First World War.

In her account of the development of the Workers' Educational Association, one would scarcely expect the author to pay attention to the future growth of the movement. Yet that is a question which perturbs many educationists, and, in the last few pages, Mrs. Stocks examines the problems which confront the Association to-day. Many educationists, she knows, believe that the Workers' Educational Association has completed the task for which it came into being and should voluntarily liquidate itself before it dies of unbecoming decay; there is a widely held belief that adult education can now be most faithfully served by government, the universities and local education authorities. Other educationists believe that there is still much for the Workers' Educational Association to do but that those in control of the movement have lost the inspiration and spirit of service which created and nourished it in its growing years; others believe that those in control are too full of tradition to adapt themselves to new ways demanded by new times. These are the kind of questions which Mrs. Stocks poses. The answers she leaves to others—and the future. Here one feels that Mrs. Stocks has been a little too peremptory with her readers, who would have welcomed her practical and precise advice on the future of the Workers' Educational Association in the light of her researches into its past and her justifiable belief that the Workers' Educational Association will be a powerful force in adult education for many years to come.

If one lesson emerges from this book, it is that the Workers' Educational Association has always been at its best when it had a cause to serve outside its own immediate adult education interests. Mrs. Stocks gives no clear guide as to which road the organization should now follow. Are we to assume that there are no educational causes to serve to-day? Or is it that educational reforms are easy to bring about during and after great wars and that there have been no major educational developments in Great Britain in times of peace? If the Workers' Educational Association wants a cause, why should it not lead the campaign to bring about the real establishment of county colleges which have been on the Statute Book in some form or other for more than thirty years? As Mrs. Stocks implies, such a cause would not lack a friend in the Chancellor of the Exchequer.

And what of the Workers' Educational Association itself? Should it be content with Tawney's advice that it must not be led into "providing education for those who can be most easily induced to undertake it" instead of "for those who need it most". There are many who believe that Tawney has failed to take account of the social movements of the past fifty years and that his advice lacks a sense of realism in 1953. Where are the great tutors of to-day? In many cases devoting their time and energy to committees and voluntary organizations which older members of the Workers' Educational Association have themselves helped to bring into being. Where are the intelligent young students of the working classes? In most cases attending degree courses at universities which were themselves created partly as a result of the efforts of older members of the Workers' Educational Association. Had the working classes of the early part of the twentieth century the radio, television, cinemas and other forms of entertainment, would they have been so assiduous in their attendance at adult education classes? If the standard of living of the working classes in 1903 had been anything like that of 1953, would Tawney's classes on economics have commanded the attention they did?

There are many who believe that noticeable developments in adult education among working classes to-day will only come through an approach which takes into account the changed nature of the people and their changed needs since 1903. The imaginative and courageous approach of the director of extra-mural studies at the University of Sheffield in providing 'day release classes' for working miners at Chesterfield has much to commend it and offers a challenge to the Workers' Educational Association. The work being done by various trade unions in providing residential courses for its members should also be of considerable significance to those in the Workers' Educational Association movement. Factory, commercial and agricultural workers are really concerned with the method of functioning of industry, commerce and agriculture and need enlightenment which perhaps might come from the Workers' Educational Association.

These are the kind of topics on which readers of Mrs. Stocks's book would have welcomed her views. In the meantime, they will be grateful for a magnificent history which does the cause of which she is so rightfully proud no mean service.

T. H. Hawkins

FINANCE OF AMERICAN HIGHER EDUCATION

Financing Higher Education in the United States
By John D. Millett. (The Staff Report of the Commission on Financing Higher Education.) Pp. xix + 503. (New York: Columbia University Press; London: Oxford University Press, 1952.) 32s. 6d. net.

THIS substantial and important book brings to an end a remarkable enterprise. For more than five years, two successive commissions of distinguished American academics have been engaged on an internal audit of higher education in the United States. They have been aided by some equally distinguished men of affairs, by the short-term services of special groups charged to investigate particular issues and continuously by a powerful staff. The inquiry seeks primarily to elucidate the effect of post-war conditions upon the economic position and prospects of the several categories of American higher educational institutions and to suggest the lines of financial policies which might properly be pursued. But that inquiry calls for a consideration and appraisal of the objectives and programmes of higher education; and much of the best—and to British readers the most instructive—of the commission's work has gone to that end.

The main commission recently published its general findings in a quite short report of two hundred pages on the "Nature and Needs of High Education". But on the way to this definitive document, the commission has issued three preliminary papers and nine volumes of preparatory studies—among them the now famous review of the 'unexportable' British practice in the provision of government assistance to the universities. The present book is the tenth and final volume of the preparatory work. It is the report presented by the staff, in the form given to it by Dr. J. D. Millett, professor of public administration in Columbia University, the whole-time executive director of the inquiry, who clearly has greatly influenced its outcome.

It follows fairly closely the structure of the commission's report. It begins by defining the main categories of higher educational services, and the distribution of these among the different types of institutions. Admittedly there is no quite consistent pattern in American higher education, whether general or professional, and few Americans desire that there should be. They like and believe in variety. But there is much more of a pattern than can be discerned at first look: and it emerges here sufficiently sharply. The second stage is a study of the elements which enter into the present costs of existing institutions and of the expenditures, capital and recurrent, which, carefully calculated on various hypotheses, will be necessary if those institutions are to hold their position and to meet the demands likely to fall upon them. Thirdly, an account is given of the present sources of income of the different types of institutions, and a projection of this account into the foreseeable future. Finally, there is a discussion of the policies to be pursued in securing economies and expanding income. At every stage, a mass of complex material is assembled and analysed with admirable fullness and clarity, and the argument enlivened with shrewd and penetrating comment. The British reader will find plenty of issues on which American experience marches with his own.

The finding is that, so long as general economic conditions remain broadly as at present, the pattern of income had better be left much as it is. State institutions, which have developed more rapidly than private institutions, and which now carry the greater part of the load, must look to increasing support from private sources and from their State legislatures. Private institutions, both colleges and universities, must look and can look confidently to fees, to endowments and capital gifts from benefactors and from sponsoring Churches or communities, to Foundations large and small, and to alumni associations. The major universities of both types may expect, particularly for their research programmes, important support from business corporations and from Foundations, and may expect also that the Federal Government will pay for services undertaken directly on its behalf. But experience suggests the need for care in settling the conditions under which grants or contracts are accepted: for future embarrassments are easily possible. In any event, the conclusion is clear—the solution of immediate and impending difficulties is not to be sought in the increasing participation of the Federal Government in the finance of colleges and universities. That way lies Federal control: and in the end that would mean "uniformity, mediocrity and compliance".

It is not for a British writer to express agreement or disagreement with the results of a study of a wholly American problem. But he may record his view that, in the preparation of this long series of reports, the commission, its staff, and the enabling Foundations have done a notable service to the university systems of many countries as well as of their own.

HECTOR HETHERINGTON

SOURCE-BOOK ON TELEVISION

Television

An Introduction to the Physical and Technical Principles of Television; with Comprehensive Descriptions of various Electrical Circuits. By F. Kerkhof and W. Werner. Translated by the late J. O'Connor Howe and G. Ducloux. (Philips Technical Library.) Pp. xv + 434 + 38 plates. (Eindhoven: N.V. Philips Gloeilampenfabrieken; London: Cleaver-Hume Press, Ltd.; New York: Elsevier Press, Inc., 1952.) 50s.

AMONG the most rapid technical post-war developments has been that of television broadcasting, particularly in Great Britain and in the United States, where public services have been established for several years. While in many cases these developments have been described in scientific and technical papers, there has been a dearth of text-books dealing with the basic principles of the subject of television, for the use of students and professional workers engaged in this field. This gap is now at least partly filled by the book under review, the authors of which are principals of the television development laboratory of Philips Industries in Eindhoven. The book is a translation—and a very good one—of one of the series in Philips Technical Library: Dutch and German editions have already appeared and a French edition is in the course of preparation.

The subject-matter has been so arranged that a reader familiar with the basic principles of radio communication can assimilate the differing trends in the basic theory and technical practice of television. Much of the text is presented in a straightforward descriptive style, with good diagrammatic and photographic illustrations: more complete explanations in mathematical form are included where it is advantageous to do so.

Although the general purpose of the book is to explain the circuits employed in television receivers, it also comprises brief descriptions of the most important circuits used in studios and transmitting stations. The reader is led in a clear and straightforward manner through chapters dealing with the physical principles of electron scanning and the various types of camera tubes to a discussion of the means of transmitting and separating the information carried by the video signals. It is here that one finds set out the characteristics of the four systems that have been defined by the International Radio Consultative Committee. These include the systems in use in Britain and in the United States, scanning at 405 and 525 lines, respectively, the so-called 'European' system with 625 lines, and the French experimental project using 819 lines.

Succeeding chapters deal in some detail with the application of relaxation oscillations to the pulse generators used for line and picture synchronization, and to the power supplies required for these. The important subject of wide-band amplifiers correctly occupies about a quarter of the book; and the later chapters deal first with the optical problems of picture presentation, including both direct viewing and projection systems, and second, with a very brief and not quite up-to-date survey of colour television. The book concludes with a chapter describing in some detail, and with complete circuit diagrams and lists of components, two television receivers for positive and negative modulation, respectively, suitable for the British 405-line system and for the 625-line standard. Although there is a short chapter on aerials and some discussion on propagation problems in relation to television, it is clear that these subjects cannot be dealt with in any detail without making the book larger than the authors may desire. It is to be hoped, however, that they may be encouraged in a future edition to make use of the extensive publications which have appeared in the literature on television since 1950.

As the first full modern study of the basic aspects of the subject, this work can be recommended with confidence both for general reading and, with the aid of the excellent bibliography provided, as a constant source of reference for more detailed study.

R. L. Smith-Rose

HIGH-ENERGY PHYSICS

High-Energy Particles

By Prof. Bruno Rossi. (Prentice-Hall Physics Series.) Pp. xiii+569. (New York: Prentice-Hall, Inc.; London: Constable and Co., Ltd., 1952.) 65s. net.

It will generally be agreed that the central problem of physics during the past twenty-five years has lain in the identification of a set of elementary particles and the establishment of their properties in interaction. In this book Prof. Bruno Rossi sets out to survey the information gathered about these particles from high-energy experiments. His interest is not with complete atoms or nuclei, but essentially in the interactions of individual particles—photons, electrons, nucleons and the variety of mesons—from a study of which one hopes to discover the laws governing the ultimate structure of things.

The general plan of the book is that the first six chapters, apart from some description of the properties of the elementary particles, are devoted to electromagnetic interactions. The remaining two chapters (amounting to nearly two hundred pages) are devoted to the interactions of nucleons and mesons. There is a difference of treatment in the two sections, in that, whereas an effort is made to present as full a theoretical account of the electromagnetic processes as can be given without the use of relativistic quantum field theory, no attempt is made to provide any theory of nuclei or mesons. Anyone familiar with the present state of meson theory must sympathize with this policy. However, there are various general considerations of meson theory which are likely to remain valid, and the comprehensive character of the book would have been improved if some account of them had been included. As it is, the later chapters of the book appear somewhat disconnected, as compared with the earlier ones.

After a short introductory account of the known elementary particles, and of the general character of the cosmic radiation, Chapter 2 is devoted to the theory of electromagnetic interactions. Here we are on well-established ground; the difficulties are those of exposition. Any theoretical physicist who has undertaken to expound, for example, the theory of Compton scattering to his experimental colleagues is aware how real these are. The classical Thomson cross-section can be derived, but a quantum theoretical derivation of the Klein–Nishina formula is accepted as being beyond the tolerable requirements of an experimentalist. The tendency is just to quote the formula and, in words or graphs, describe its consequences. This path is in many cases followed by Prof. Rossi, and he is very successful in the clarity of his exposition (though I must disagree with his statement on p. 13 that no classical analogue exists to the Compton scattering). In other cases, as in the treatment of the ionization produced by the passage through matter of fast charged particles, or of the production of bremsstrahlung, where there are semi-classical descriptions available for the phenomena, these are well presented. Incidentally, the author's interest in statistical fluctuation problems is shown by a good account of what is sometimes called the 'Landau effect'—the fluctuations in energy loss by collision.

There follows a brief description of the mode of operation of most of the detectors used in nuclear physics, sufficient to provide a background against which the experimental material can be assessed. Chapter 4 contains a review of some of the basic properties, including the decays, of the various elementary particles. In part this account is historical; thus the cosmic ray experiments leading to the discovery of mesons and their decay are described as well as the later experiments with artificially produced mesons which have enabled the properties to be more precisely established. This chapter also contains a short account of heavy mesons, now rather out of date, which serves to illustrate the difficulties of giving in book form an adequate account of a fast-developing subject.

The next two chapters are devoted, respectively, to cascade shower theory and to a rather miscellaneous collection of experiments on high-energy electromagnetic interactions. The book ends with the two chapters on nuclear interactions—the first dealing with artificial sources and the second with cosmic radiation. An interesting feature of this last chapter is an admirable set of thirty-two photographs of high-energy nuclear events. The information from artificial sources is complete up to early 1951. It is perhaps in this chapter on artificial sources that the need for some theoretical interpretation of the meson phenomena is most strongly felt.

In conclusion, Prof. Rossi is to be congratulated on providing such a full survey of a large subject within a single volume. As a readable account of certain of the more complete topics in high-energy physics, and a reference work describing the more recent experiments up to 1951, this book can be warmly recommended.

J. C. Gunn

A Source Book in Chemistry, 1400–1900

Edited by Henry M. Leicester and Herbert S. Klickstein. (Source Books in the History of the Sciences.) Pp. xvi+554. (London: McGraw-Hill Publishing Co., Ltd., 1952.) 64*s*.

FOR this contribution to the series "Source Books in the History of the Sciences", an international group of scholars acted as advisers. The selection employed, restricted "to material which illustrates the development of chemical theory only", pays frequent tribute to the acumen of "The Alembic Club Reprints" and Ostwald's "Klassiker". Some one hundred and forty excerpts are provided, with brief notes on the eighty authorities who are cited in the list of contents.

Even so prosaic an anthology will arouse contention. Some will look for Lomonosov, Higgins, Stas or Newlands; others will note the omission of original papers on kinetic theory; and many will argue that the discovery of the inert gases has influenced "the development of chemical theory" much more than Agricola's recipe for mineral acid. It would be interesting to know on what system Dulong is so distinguished to the disadvantage of Petit, why "Wöhler and Liebig" on the benzoyl radical appears under Wöhler, and why Dalton is represented in part by a lengthy extract from Thomas Thomson. Richter is illustrated by a "Table of Richter's equivalents" which is in fact a table calculated and composed by E. G. Fischer. There is a degree of confusion on the origin of footnotes (author, translator, editor) and a few ill-advised intrusions in the text, as, for example, an unidentified one "(i.e. carbon monoxide)" in a paper by Cavendish (p. 148). There are a useful author index, and a bibliography of biographies. There is no subject index.

The translations specially made are in general business-like and clear. The contemporary translations of older works are charming and well chosen. There are notably few misprints. There is great advantage in this collection of an English version of so many pregnant essays between one pair of covers, and the volume is a proper candidate for the staff bookshelf in every place where chemistry is seriously taught.

ANDREW KENT

The Phase Rule and its Applications

By Alexander Findlay. Ninth edition, by Prof. A. N. Campbell and Prof. N. O. Smith. Pp. xii+494. (New York: Dover Publications, Inc., 1951.) Paper, 1.90 dollars; cloth, 5 dollars.

CONSIDERED by some as a classic and by many as the standard work, Findlay's "Phase Rule", when first published in 1904, had 313 pages; in the eighth edition of 1938 there were 327 pages. Owing to unceasing research and the shift of emphasis, the eighth edition no longer reflects a comprehensive view of the subject. Accordingly, the authors—they are more than revisers—have rebuilt the book from a new selection of available knowledge. Their own contributions to the literature and their awareness of the needs of students make them well fitted for the task. They have eliminated matter of diminished importance, greatly increased the number of references and illustrations and much extended the range of topics discussed.

Thus the authors give entirely new treatment both of ternary liquid-vapour equilibria and of solid solutions in ternary systems. Included also are: phase changes in the cooling of ternary melts, quinary systems of salts and water, critical phenomena in binary systems, salting out, soap systems, fuming liquids, the free-energy basis of ternary and condensed systems, and the experimental determination of freezing-point diagrams.

The clear style of writing, the explanatory notes, the graphical thermodynamic deductions of some familiar equilibrium diagrams, and the frequent use of solid models should afford valuable help to students. The extended scope and extensive changes make this in all but name a new book and it should rank as the standard work in English on this subject.

G. F.

Statistical Year-Book of the World Power Conference

Annual Statistics for 1948–1950, with some Supplementary and Revised Statistics for Earlier Years and Available Statistics for 1951; some Additional and Revised Data on Resources. Edited, with Introductory and Explanatory Texts, by Frederick Brown. Pp. 163. (London: World Power Conference, 1952.) 35*s*. net.

THE third post-war issue of the "Statistical Year-Book of the World Power Conference", which has now become a biennial publication, gives statistics for 1948–50 with additional and revised information for earlier years and the available statistics for 1951. There are also some additional and revised data on resources. Like its predecessors, the present issue contains statistics of the productions, stocks, imports, exports, consumption of power and sources of power in all the countries of the world from which it was possible to obtain information. Data on resources are included only where important additional information has become available. The power sources are coal, lignite, peat, coke, manufactured fuel, wood, gas, water-power and electricity. Most of the statistics were supplied by the national committees of the World Power Conference; but, to a substantially greater extent than in previous issues, statistics have been reproduced from publications of the United Nations and from government sources. Preliminary tables give the area and population of all countries; the population figures are estimated for each year during 1948–51 and also for the last census. All measurements are on the metric system.

The Ant World

By Derek Wragge Morley. (Pelican Books.) Pp. 191+8 plates. (London: Penguin Books, 1953.) 2*s*.

THE publishers of Pelican books have again performed a useful service to natural history by the publication of this book on ants. Wragge Morley began to study ants when he was fourteen, read his first research paper two years later, and has been an 'ant man' ever since. Now, at thirty-three, he brings his long experience together in a form which is both interesting and scholarly to describe a group of insects which, although little known, comprises some fifteen thousand species—a number which is constantly being enlarged by the discovery of new ones. Harvesting ants, soldier ants, mushroom-growing ants, spinning ants, ants which live in small and large communities, ants a millimetre long and ants 3¼ in. long, are all described from the points of view of history, behaviour, ecology and physiology. Morley also pays attention to the considerable economic importance of ants to man. The book is admirably illustrated with line-drawings and photographs.

STONEHENGE IN THE LIGHT OF RECENT RESEARCH

By R. J. C. ATKINSON

Department of Prehistoric Archæology, University of Edinburgh

DURING June and July of this year, excavations were undertaken at Stonehenge by Prof. Stuart Piggott, Dr. J. F. S. Stone and myself as part of research planned with the view of the eventual publication by the Society of Antiquaries of a definitive report on the monument and its associated structures. The season's work had three objectives: first, to examine in detail the course of the Stonehenge Avenue, and in particular to confirm or disprove the existence of the branch alleged by Stukeley in 1740 to run towards the Cursus, which has not since been reliably observed; second, to seek evidence for the date and purpose of the two rings of pits, known as the *Z* and *Y* Holes, which encircle the stones; and lastly, to examine the relationship of the Heel Stone to the Avenue within which it stands, and to establish more firmly the position of both in the sequence of construction.

At the first eastward bend in the Avenue, some 1,700 ft. north-east of Stonehenge, careful observation of the surface, aided by probing and by electrical resistivity surveys, revealed no trace of the supposed branch. Two ditches were found, however, and proved by excavation, which corresponded closely with the position recorded by Stukeley for his branch. Neither was connected with the Avenue proper nor with the other; but it is clear that, with the help of a little imagination, they could, and almost certainly did, mislead Stukeley into asserting that they formed a branch of the Avenue leading in the direction of the Cursus. Their date is unknown; the western ditch is upwards of 500 ft. in length, and may be a boundary ditch of the first millennium B.C.; the eastern ditch, only some 100 ft. long, is clearly of more recent date and was shown to have been dug after the ditches of the Avenue were completely silted up.

The *Z* and *Y* Holes chosen for examination (*Z* 16 and *Y* 16) lie south-west of the stones, immediately west of the axis. They proved to be oval pits, 5–6 ft. long and 4 ft. wide, with sides sloping steeply to a flat bottom, sub-rectangular in plan. The chalk sides themselves were almost unweathered, and were covered by a few inches of much-weathered chalk rubble, the primary silting formed by the initial disintegration of the sides during the first few years of exposure. The remainder of each pit contained secondary earthy silting, extending almost to the bottom, with a number of flint nodules in the lower levels. Finds from the primary silting comprised a single sherd of pottery, dating from the second millennium B.C., and a few very small chips of bluestone, but no sarsen fragments or pottery of later date. The secondary silt yielded numerous chips of both sarsen and bluestone, and pottery of the first few centuries B.C. and A.D.

The contents of the holes showed conclusively that, once dug, they were left open, and that the secondary silt accumulated very slowly over a period of many centuries. In view of the known ability of earthworms to bury small objects, the presence in this secondary silt of Iron Age pottery, even at low levels, can therefore no longer justify the ascription of the *Z* and *Y* Holes to that period. That the holes were dug after the erection of the sarsen stones was already known from the excavations of 1919–26; the new excavation suggests that they were dug before the erection of the bluestones in their present setting. For, had the dressing of the bluestones taken place before the excavation of the holes, the quantity and size of the bluestone fragments in the early silting would almost certainly have been greater; the scarcity and small size of the chips actually found may be ascribed more convincingly to abrasion between bluestone monoliths which were being manhandled on the site but had not yet been dressed to shape or erected.

The purpose of these holes is still unknown. It is noticeable, however, that they are of a suitable size and depth to serve as emplacements for the existing bluestones; and it can scarcely be a mere coincidence that their number, fifty-nine (one hole, *Z* 8, is missing, its position being occupied by a sarsen stone which had apparently fallen before the holes were dug), is identical with the best estimate of the original number of bluestones in their present setting (forty in the circle, nineteen in the horseshoe). It may thus be suggested, as more than a pure speculation, that the *Z* and *Y* Holes were dug, some time in the latter half of the second millennium B.C., as sockets for the bluestone monoliths; that this purpose was abandoned, for reasons unknown, before their erection; and that the holes were left open, while the bluestones were afterwards dressed and erected in their present positions.

At the Heel Stone, work was confined to a single trench running from its south-east side across the ditch which encircles it and through the adjacent eastern bank and ditch of the Avenue. It was found that the stone had been erected from the west, and that, as at Avebury and elsewhere at Stonehenge itself, the opposite side of the hole had been furnished with a row of upright anti-friction stakes, designed to prevent the toe of the stone from digging into the side of its socket when it was being hauled upright. Decayed remains of these stakes were found *in situ* against the south-east face of the stone at its base, while above, where soil had gradually filtered in to replace the rotted wood, several fragments of Beaker pottery were discovered. At the same level were numerous fragments of sarsen and bluestone, but none occurred lower down. The pottery can be dated 1700–1600 B.C.; and when allowance is made for the decay-period of the stakes, it may be concluded that the stone was erected, at latest, around 1700 B.C., and very possibly earlier. It is therefore probably contemporary with the earliest constructions on the site, the ditch, bank and Aubrey Holes. A carbon-14 test of charcoal samples excavated from Aubrey Hole 32 in 1950 gave the date of this earliest phase as 1848 B.C. ± 275 years.

The narrow, steep-sided ditch surrounding the Heel Stone appears to have been filled up deliberately shortly after it was dug. In this filling was a single chip of unweathered bluestone (rhyolite). As the ditch was presumably dug immediately after the erection of the stone, and as the latter appears to belong to the earliest monument, it follows that at least one foreign stone is likely to have formed part of this monument. There is evidence, however, that at this time the majority of the bluestones stood as a separate monument some twelve hundred yards north-west of Stonehenge and were not moved to their present site until after the erection of the sarsen stones.

The surface of the deliberate filling of the Heel Stone ditch was covered by the tail of the Avenue bank, which shows that the latter, and its ditch, must be later than the stone. The absence of fragments of sarsen and bluestone from the bank material and from the primary silting of the ditch strengthens the hypothesis that the Avenue antedates the erection of the stones of Stonehenge.

The date of the erection of the sarsen stones, hitherto uncertain because based on circumstantial evidence only, can now be placed with some confidence around 1500 B.C. This has been made possible by the chance discovery of representations of Bronze Age weapons on two of the stones. These comprise a hilted dagger and four axe-heads on Stone 53, and at least eleven similar axe-heads on Stone 4. The axes are all of the 'hammer-flanged' type, characteristic of the British Early Bronze Age, and manufactured, chiefly in Ireland, from 1600 B.C. to 1400 B.C. The presence here of these obviously ritual representations points to the existence in Britain of an axe-cult comparable to the cult of the double-axe in the contemporary Minoan civilization of Crete. That there may be some actual connexion between these cults is suggested by the dagger. This is unlike any weapon current in the Bronze Age of Britain or Western Europe, but is an accurate representation of a type used in the central Mediterranean from 1600 B.C. to 1500 B.C. and best paralleled from Shaft Grave VI at Mycenæ. Its exotic nature makes it highly probable that the carving was executed at Stonehenge within the lifetime of someone who was personally familiar with this type of weapon in its homeland; in other words, not later, say, than 1470 B.C. It follows, therefore, that the sarsen stones were erected before this date. It may be added that this dagger affords presumptive evidence that the architect of Stonehenge was himself a Mycenean, a suggestion which has already been prompted by the architectural refinements exhibited by the monument.

The evidence reviewed above, when added to that from previous excavations, makes it possible to set out, with greater confidence than before, the following probable sequence of phases of construction at Stonehenge. (1) 1900–1800 B.C.: Construction of ditch, bank and Aubrey Holes; erection of Heel Stone and at least one bluestone, perhaps in the centre. (2) Construction of the Avenue. (3) 1500 B.C.: Dismantling of bluestone(s) of phase 1; erection of the sarsen stones. (4) Digging of the *Z* and *Y* Holes, possibly for reception of bluestones derived from the dismantled 'Bluestonehenge' twelve hundred yards away. (5) Plan of phase 4 abandoned; bluestones dressed and erected in their present positions.

INTERNATIONAL FEDERATION OF UNIVERSITY WOMEN

ELEVENTH CONFERENCE

"HUMAN Values in the Technical World" was the theme of the Eleventh Conference of the International Federation of University Women held recently at Bedford College, London. The theme is topical and appropriate for a Federation the aim of which is the encouragement of scholarship and the promotion of understanding among university women of the different nations of the world. Two methods of approach were used: a series of three public lectures by distinguished speakers, each of whom dealt with a special aspect of the subject, and discussions by small groups of Conference members of different nationalities and varied interests.

The conference was attended by about 750 members from twenty-eight countries, and included representatives of almost every kind of profession from the director of the Meteorological Office in Iceland to an Italian woman graduate who is a farmer. Conference members were pleased to hear that Dr. Louise Pearce, third vice-president, had recently been honoured by the award of the Order of the Lion and a gift of 10,000 dollars from the Belgian Government. This award was for her share in the discovery of tryparsamide, a drug which has proved extremely valuable in the treatment of sleeping sickness in the Belgian Congo.

It was announced at the conference that nine international fellowships will be awarded in 1954. There will be two international federation fellowships, named the Ida Smedley Maclean Fellowships in memory of the late Mrs. Smedley Maclean, an English biochemist and the originator of the Fellowship Fund. A new Irish Fellowship is to be given in honour of Prof. F. E. Moran, president during 1950–53 and the first Irish president of the Federation, and six fellowships have been endowed by members of the American Association. A fund for the provision of one or more fellowships and grants to be called the Winifred Cullis Fund is to be established in honour of Prof. Winifred Cullis, one of the founder members of the Federation. Since its foundation in 1920 the International Federation has awarded seventy-eight fellowships and eighteen grants to scholars of twenty-four different countries.

The officers of the International Federation for 1953–56 were elected at the conference, and the new president is Miss Dorothy Leet, of the American Association of University Women, who is president of Reid Hall, the American Education Centre in Paris. Since 1949 Miss Leet has been the International Federation's consultant to Unesco. The three vice-presidents are: Dr. E. C. Batho, principal of Royal Holloway College, University of London, Mrs. Schouwenaar-Franssen, of the Netherlands, and Mrs. Dorothy Forsaith, of Australia. The new honorary treasurer is Ing. Adèle Racheli, of Italy, whose special field of study is mechanical engineering and who is a patent agent with offices in Milan, Rome and Switzerland.

The three public lectures on the theme, "Human Values in the Technical World", accepted as a fact the interdependence of the nations of the world, brought about by science, and the problem studied was the means whereby man might reach his highest excellence in these conditions. Speaking on "London

Town'', Sir Henry Self, president of the British Electrical Development Association, traced the part London has played towards scientific development in its impact on human thought and values. He expressed the fear that science has made this earth so worth-while a habitation that it opens up the menace of "soft living" and has at the same time produced devastating means of destructive war. Scientific achievement has been attained by self-sacrificing effort, stirring adventure and resolute pursuit of truth for its own sake; these are precisely the human values threatened to-day. The sweeping advances made in the study of astronomy, mathematics and physics at the time of the Renaissance prepared the way for the revolution of the following century which produced a scientific interpretation of life and the world in terms of mechanistic determinism and materialism. At the same time the Reformation asserted the responsibility of the individual. The movement began as an adventure of man's personality responding to his intellectual confidence that truth must prevail. But gradually during these centuries God was reduced successively to the role of maintaining order, and then to the point where there was "no need of such a hypothesis". Gradually, however, the idea that the universe is made up of living objects in full and intimate interaction took shape. Sir Henry traced the history of experimental work in the nineteenth century, mentioning particularly work in spectrum analysis. He mentioned the controversy about the theory of evolution and said that scientists to-day recognize a fundamental harmony of things. Science, concluded Sir Henry, is one channel by which God speaks to man and conscience is another. This is the way whereby human values might be preserved in the technical world.

The second lecture, "Science and the Discovery of Human Values", was given by Prof. Arthur H. Compton, chancellor of Washington University. He does not support Sir Henry Self's fear of the threat of barbaric power. Technology in itself, he said, gives its distinctive meaning to life by revealing the interdependence of all men and all nations. The goal of the scholar is the vision of excellence; technology gives him the power to make the lives of others excellent and to enable them to grow to their best, thus finding his own fulfilment. Long ago Pythagoras said that the scholar sought to learn how the world was made in order to find a better way of life. We of this age have been brought face to face with the vastness of the universe; thanks to the advances of technology it is in our power, and, indeed, it is our responsibility, to affect the lives of others. It is a matter of vital significance that adaptation to life in the modern world demands increasing emphasis on the human virtues: success in science means loyalty to truth, concern for reliable knowledge; technology calls for the skilled expertness that comes from experience combined with specialized knowledge; work in any social organization requires willingness to co-operate, consideration for one's fellows and a desire to promote the task on which the group is engaged. Banishing the spectres of starvation and premature death from disease is not enough: the essential dignity of man is all-important and each individual must have the opportunity of playing his part and taking responsibilities. Science improves the means with which we work towards our goal and enlarges our choice of goal. Losing ourselves in the effort to give others the opportunity to find each his own excellence is a condition of survival; so can we find our own souls and so can the humanities be preserved.

"Organization and Personality" was the subject of the address given by Prof. P. C. Mahalanobis, statistical adviser to the Government of India and vice-chairman of the United Nations Statistical Commission. He said that the technical world and the advances of science must be accepted; there is no retreat, but the problem is to adapt the personality of man so as to attain its highest perfection in a world of ever-increasing power. The basis of the development of personality lies in the relationships of human beings; these relationships develop gradually, from the home to the school, and widen from the national to the international level. Social organization in the machine age is tending to the submergence of personality: skilled labour gives place to unskilled, craftsmanship is displaced, automatic controls take over. This is the price we are paying for technical power. Conflicts arise on every level—between capital and labour, town and village, between nations and blocks of nations. Science can enable us to provide more food, more clothes and medicines. At every new stage of scientific development humanity is faced with a crisis, and a growth of personality is needed to meet it. We have to learn to use our power for the general good. Some of the basic biological and emotional human values remain unchanged everywhere. Our "institutional values", such as means of preparing food, can develop, and here science increases the scope greatly. Cultural unities, such as that of Europe, represent a "national value". International contacts and values have become a necessity of the modern world as we are drawn ever closer together by technology. The danger to modern society lies in making a social merit of having more and more things, but herein lies a source of unbalance and greed. We must learn to grow into that wholeness of personality which finds its self-expression in a joy in things and not merely in possessing. Our goal must be to transcend the little cell and to work towards a unity in diversity, not by eliminating our differences as nations, but by creating a deeper harmony in humanity and friendship.

The main theme was divided into various aspects for study by groups of conference members—a balanced education for full citizenship, methods of mass education, the ethical basis of human values in a technical age, the human factor in the organization of work and the impact of modern techniques on non-industrial communities. In reporting the findings, Dr. Marguerite Henrici, organizer of the groups, said that they are not yet the official opinions of the Federation, but the results of discussions during the conference. Once again, naturally, the importance of the individual was emphasized. The first group recommended that each individual should be educated to think clearly and effectively, to form critical judgments, to practise a concern for the welfare of others, since citizenship demands a realization of a duty to others near and far. A balance between intellectual and social education should be maintained, and in the living community of the school each individual should have his rights and responsibilities. While a just pride in the national heritage is to be encouraged, the obligation to the wider international community must not be forgotten. Small classes and more teachers are desirable.

Mass education entails education through life: any kind of rich and varied experience which evokes a greater appreciation of life contributes to this. Again, the value of the individual was stressed and it was recommended that the Federation should use its influence to make mass media such as films and radio less sensational and more inspiring to the individual. Cheap means of printing and the suppression of over-nationalistic text-books would be helpful, too, as would schemes for the exchange of students and teachers between rural schools and others. It was further recommended that the value of the humanities in general education should be emphasized, while recognizing the importance of scientific and technological factors.

The group which discussed the ethical basis of human values came to the conclusion that the essential value at which man ought to aim is the increasing development of those powers of soul and spirit which contribute to build up a harmonious personality and society. Special efforts should be made to counteract the levelling tendencies of technology by stressing the necessity of individual decision.

In studying the organization of work, a further group considered it should be so arranged as to protect the personality of the individual. Suggested practical means to this end were: vocational guidance for all, and an effort to find ways of overcoming the effects of monotonous work.

The fifth group, in dealing with the impact of modern techniques on non-industrial communities, reached the conclusion that the greatest precaution should be used in the introduction of foreign ways and standards of living into non-industrial countries. Accepting the fact that technology's greatest contribution lies in the service of others, this group stressed that this service can be performed on the spiritual plane as well as on the material.

In summing up the findings of the groups, Dr. Henrici said that in this time of transition and crisis the threat to human values comes not only from external nature but also from civilization itself. It is the task of educated people everywhere to seek the truth with fervour and to follow it with courage. It is a more difficult task than to live according to the precepts of the loud-speaker. The power of decision lies with each individual and therefore with the human race. The individual is not himself responsible for the decisions taken by the race, but in living his daily life he can influence them for good or ill.

PARTICLES OF COSMIC RADIATION

An international conference on cosmic radiation, organized by the University of Toulouse and under the patronage of the International Union of Pure and Applied Physics, was held at Bagnères de Bigorre during July 6–12. The president of the conference was Prof. P. M. S. Blackett, and the secretary-general Prof. L. Leprince-Ringuet. In opening the conference Prof. Blackett said that it had been decided to restrict the discussion in the main sessions to the narrow but important field of V-particles and heavy mesons. It was hoped thus to make an effective contribution to a subject of great contemporary interest for the development of our knowledge of elementary particles. This aim was reflected in the attendance at the conference, and among the two hundred members were representatives of many of the laboratories actively engaged in the subject.

The main sessions of the conference were divided into two groups. In the first seven, the experimental facts were described and discussed; in the last three, the whole body of evidence was reviewed, and an estimate made of the present state of knowledge. In describing the most important results and conclusions, it will be convenient first to consider particles more massive than the neutron; and secondly, those intermediate in mass between the π-meson and the proton.

Particles Heavier than the Proton

It is now established that the heavy neutral V-particles discovered by Rochester and Butler (V_1^0) decay into a proton and a negative π-meson with an energy release of about 37 MeV.:

$$V_1^0 \rightarrow P + \pi^- ; \quad Q = 37 \pm 3 \text{ MeV.}$$

The mean lifetime of the particles is $\sim 3 \cdot 3 \pm 1 \cdot 0 \times 10^{-10}$ sec. There is good evidence that they can be produced in nuclear interactions in which the available kinetic energy is insufficient to provide all their rest-mass. They are therefore believed to result from the transformation of nucleons, and, in this sense and since they decay into protons, they may be termed 'excited nucleons'. An outstanding problem of great interest is whether the particles are commonly produced singly or in pairs, a question which it may be possible to resolve by determining the minimum energy required for their production in the collision of protons and π-mesons with nuclei.

There is now strong evidence from work with photographic plates for the existence of charged particles more massive than the proton, each of which decays into a neutral particle and a π-particle according to the equation:

$$J^\pm \rightarrow N + \pi^\pm .$$

If the secondary neutral particle is a neutron, the release of energy, Q, is $\sim$ 130 MeV., and the mass of the parent particle, m_J, $\sim$ 2,360 m_e. Five examples have now been observed in photographic emulsions, in three of which the primary particles decay in flight. The mean lifetime appears to be of the order 4×10^{-11} sec. There is tentative evidence for an alternative mode of decay $J^+ \rightarrow P^\pm + \pi^0$, but this remains to be confirmed.

There is good evidence from experiments with Wilson chambers, but also not decisive, for a massive charged particle which decays into a negative π-meson and a neutral V_1^0-particle according to the equation $\Lambda^- \rightarrow V_1^0 + \pi^-$. In addition to the original event, which can be interpreted in this way, found by Armenteros *et al.*, three similar examples have been observed by Leighton and his colleagues. It is possible that the particles J and Λ are identical, in which case their mass is $\sim$ 2,700 m_e.

Further examples have now been observed of the process, first observed by Danysz, in which a heavy nuclear fragment ejected from a nuclear explosion reaches the end of its range and disintegrates. It appears that π-mesons are frequently emitted as one of the products of the secondary disintegration. It is possible that these events are due to the presence, in the nuclear fragment, of a nucleon in an excited state; but alternative explanations cannot at present be excluded.

Heavy Mesons

Of the heavy charged mesons with masses in the interval 900–1,500 m_e, it is established that particles of mass 970 ± 5 m_e exist which decay into three π-mesons. The particles are referred to as τ-mesons; $\tau \rightarrow 3\pi$. Seventeen examples have been recorded in photographic plates, in all of which the particles decay 'at rest'; and of the fifty-one secondary π-particles from these events, eleven have been observed to reach the end of their range. Eight of them have thus been identified as positive, and three as negative, π-particles. This fact, and the observed co-planarity of the directions of emission of the three π-particles from each decaying τ-meson, make it probable that all, or most, of the particles which decay in this mode when arrested in photographic emulsions are positively charged. A few examples of the decay 'in flight' of τ-mesons have been observed in Wilson chambers. In one case, the parent particle was negatively charged. The τ-mesons observed in cloud-chambers occur infrequently compared with charged V-particles, $N_{\tau\pm}/N_{V\pm}$ being $\sim 1/20$.

It is established that some heavy mesons, when arrested in photographic emulsions or in metal plates, decay with the emission of μ-mesons. This follows, on one hand, from the direct observation of the β-decay of the secondary mesons, or from mass-measurements in photographic plates; and, on the other hand, from experiments with expansion chambers in which the secondary particles are observed to traverse a total distance equal to several 'interaction-lengths' in metal plates, without giving decisive evidence for a nuclear interaction. The energy of the secondary μ-meson varies widely—from very low values up to at least 200 MeV. It is therefore necessary to assume that the μ-meson is accompanied by at least two neutral particles. Particles decaying in this mode are referred to as κ-mesons; $\kappa \rightarrow \mu + 2$ neutral particles.

Experiments with photographic plates suggest that heavy mesons may sometimes decay with the emission of a π-meson of energy $\sim$ 110 MeV. The evidence is not decisive; it receives no support from observations with cloud chambers, but the latter are not inconsistent with the view that heavy mesons sometimes decay in this mode. Since the energy of the secondary π-mesons appears to be unique, the transformation is written, tentatively: $\chi \rightarrow \pi + 1$ neutral particle.

Experiments with Wilson chambers indicate that photons, with energy 100–200 MeV., are sometimes produced in the decay of heavy particles. The photons, detected by the small cascades of electrons to which they give rise, appear to recoil from the secondary charged particle. The observations are compatible with a decay of the parent into two particles only, a charged particle and a photon, but this interpretation does not necessarily follow from the observations and must be treated with reserve.

All the direct measurements, made hitherto, of the mass of heavy charged mesons which come to rest and decay into a single charged particle are consistent with the view that all the particles have masses near, or equal to, that of the τ-meson. This result, if taken alone, makes it permissible to assume, tentatively, that the particles distinguished phenomenologically as τ-, κ- and χ-mesons represent alternative modes of decay of particles of a single type, but it does not prove this assumption to be true.

There are two pieces of experimental evidence which suggest that among the heavy mesons are some which have masses significantly greater than that of the τ-meson. The first piece of evidence is the observation of the maximum energy of the μ-mesons produced in the decay of κ-mesons. If the τ-meson has a mass of 970 m_e, the maximum energy of the μ-mesons, set by the conservation laws and assuming both neutral particles to have negligible rest-mass, is $\sim$ 150 MeV.; the corresponding values of momentum, p and $p\beta$, are $\sim$ 233 MeV./c and $\sim$ 211 MeV./c, respectively. Observations by expansion chamber give no evidence for secondary particles with energies greater than this limit. On the other hand, measurements with plates provide several examples in which the secondary particles appear to have values of $p\beta$ substantially greater than that corresponding to the limit. It is well known that determinations of $p\beta$ by the scattering method can give high values due to statistical fluctuations. The probability that the high values in question are to be so interpreted appears, however, to be small—less than 1 per cent. To bring these observations into accord with the assumptions that $\tau \equiv \kappa$ or that $m_\tau \sim m_\kappa$, it is necessary to assume either that there are unsuspected sources of error in the measurements, or that there are alternative physical processes involved. It is possible, for example, that some of the heavy mesons observed to decay are negatively charged. If weakly interacting, they might then decay while moving with high velocity in bound orbits around nuclei; and if so, the energy spectrum of the secondary particles might be greatly modified as compared with that of the positive particles. Such an effect is believed to exist in the case of negative μ-mesons captured by nuclei of low atomic number.

The second piece of evidence is that measurements by the photographic method of the masses of heavy mesons directly emitted with great velocity ($\beta \sim 0 \cdot 7$) from nuclear disintegrations give a mean value of about 1,210 m_e; and there are no individual values in the mass spectrum less than 950 m_e. It is reasonable to assume tentatively that the fast heavy mesons created in the high-energy events are identical with those with approximately the same velocity, observed in experiments with Wilson chamber, which appear to have masses of the order of 920 ± 40 m_e. The later values are not significantly different from those of the slow particles already discussed.

The above apparent contradiction in the mass values can be resolved, and the assumptions that $\kappa \equiv \tau$, or that $m_\kappa \sim m_\tau$, can be maintained, if it is assumed that the mass measurements by the photographic method are subject to unrecognized systematic errors. Alternatively, it may be assumed that the heavy particles of mass $\sim$ 1,210 m_e are indeed emitted from high-energy disintegrations, but that they decay in flight, with a mean lifetime of the order of $\sim 3 \times 10^{-11}$ sec., and transform into particles of mass $\sim$ 970 m_e. In general, such a transformation should lead to a deviation in the track of the particle, but the deviations may be small if most of the difference in mass appears as the rest-mass of the secondary neutral particle or particles.

Nuclear Capture of Negative Heavy Mesons

There appears to be a large disparity between the number of heavy mesons observed to decay in nuclear emulsions and the number which interact with nuclei. The evidence obtained with Wilson chambers shows that positively and negatively charged V-particles occur with approximately equal frequency. Since the particles appear to be directly created in nuclear interactions, it would be reasonable to assume that they are strongly interacting. If so, when arrested in solid substances, they would be expected to produce observable disintegrations. Very few such disintegrations have been found, although many laboratories have made a well-directed search.

It is difficult, at present, to make a reliable estimate of the ratio of the number of heavy mesons decaying to the number producing a recognized nuclear interaction because of the different methods of search employed in different laboratories, but a conservative estimate suggests that it is at least five to one. If the particles observed to decay are all positive, it then follows that only about a fifth of the negative heavy mesons, when arrested in photographic emulsions, produce effects due to nuclear capture comparable with those due to negative π-mesons. Alternatively, some of the particles may be weakly interacting so that, as with μ-mesons, some of them, even when negative, may decay.

Neutral Heavy Mesons

Of the neutral particles less massive than the proton, it is now established that there is one type which decays into two charged mesons, one of which is a π-particle, and probably both: $\theta^0 \rightarrow \pi^+ + \pi^-$; $Q = 214$ MeV. The mean lifetime of these particles is $\sim 10^{-10}$ sec. If the secondary charged particles are both π-mesons, the mass of the parent particle $m_{\theta^0} = 971 \pm 10\ m_e$, a value equal to that of the τ-meson within the limits of experimental error.

There is evidence for other types of heavy neutral particles, referred to as V_2^0, which appear to decay into a heavy meson and a light meson (π or μ), but it remains to be confirmed.

The conference gave an impressive demonstration of the great profit to be derived from meetings between representatives of different scientific traditions. The presence of many experts in the various experimental methods ensured a most informed and critical approach to the important questions which were reviewed, and the conference was memorable for the very serious level of the discussions, and the cordial relations between its members.

C. F. POWELL

PROGRAMME OF AUSTRALIAN ANTARCTIC EXPLORATION

By SIR DOUGLAS MAWSON, O.B.E., F.R.S.

DURING the past six years, the Commonwealth Government of Australia has, through its organization known as the Australian National Antarctic Research Expedition, prosecuted scientific investigations in the Far South. As long ago as 1939 tentative plans were formulated to continue with the scientific exploration of Antarctica. At that time it was proposed to organize such work under the ægis of the Australian universities, with the expectation of maintaining one or more shore research stations on the Antarctic mainland, there to be serviced from Australia by employment of the *Wyatt Earp*, which in 1939 the American explorer Lincoln Ellsworth had disposed of to the Commonwealth Government. However, the advent of war postponed such proposals and the *Wyatt Earp* was placed under the care of the Royal Australian Navy.

At the termination of hostilities the matter was again pressed, representations to the Government being made by the National Research Council.

Eventually, early in 1947, the Government agreed to meet the cost of refitting the *Wyatt Earp* as required for explorations in Antarctica and to establish and conduct research stations in the subantarctic on both Macquarie Island and Heard Island: the former about 900 miles S.S.E. of Hobart, the latter about 2,500 miles S.W. of Perth. Group-Captain Stuart Campbell, who had had Antarctic experience as chief aviator of the B.A.N.Z.A.R. Expedition of 1929–31, was seconded to be chief executive officer in command of the undertaking. Much was accomplished in that first year. On Macquarie Island and on Heard Island well-equipped stations were established and operated during the year 1948. Also in the summer of 1947–48, with Campbell on board and a staff of several scientists, including Mr. P. G. Law, the *Wyatt Earp*, manned by a naval crew under the command of Commander Karl Oom, made a short, late-season cruise into the pack-ice, including a visit to the Balleney Islands.

The report furnished at the conclusion of the cruise indicated that the *Wyatt Earp* was too small for the undertakings planned, her capacity being barely sufficient for the naval crew, leaving insufficient accommodation for the transport of shore-station staff and their equipment. The antarctic section of the programme was then suspended until a suitable vessel of greater capacity should be made available. The sub-antarctic stations, which were at that time being serviced annually by a naval L.S.T. vessel, were in the meantime to continue in operation.

Group-Captain Campbell returned to his post-war assignment in Commonwealth Civil Aviation Controls, and for several years since has been on duty in Siam as Commonwealth officer on loan to help reorganize civil aviation in that country.

In the meantime, the Department of External Affairs established an Antarctic Division to take care of Australian activities in the Far South. Mr. P. G. Law is the officer in charge.

The stations at Macquarie Island and at Heard Island have continued to function without a break, the personnel being relieved each year by the transport of new staff and supplies. The meteorological programme has been specially stressed, since it is hoped that by a detailed study of the movements of air masses between Antarctica and Australia the possibility of forecasting the weather of southern Australia may be enhanced.

Considerable attention is being given to geophysics, radiophysics and cosmic ray studies, and there is ample provision for cartographical, biological and geological activities. Already there has been amassed a very substantial and valuable addition to knowledge of the sub-antarctic in the Australian region.

What is now due to be undertaken is the extension of this programme to the antarctic mainland. This depends upon the provision of adequate transport. The design of a vessel especially to meet the needs of exploration within the pack-ice zone was submitted through the Navy Department, but, on account of cost, has been shelved. Nevertheless, provision has now been made for the establishment next summer of a base station on the antarctic mainland. Final approval and an outline of plans was recently notified by the Right Hon. R. G. Casey, Minister of External Affairs.

A Danish vessel, the *Kista Dan*, designed for navigation in the Greenland seas, has been chartered as a transport. As this vessel has also to relieve the Heard Island staff during the same antarctic cruise, the party to be established on the mainland will comprise not more than nine or ten men.

This antarctic mainland party will undertake during 1954 reconnaissance operations preparatory, it is hoped, to more extended developments in succeeding years. Scientific operations during the first year of occupation will be concerned mainly with geographical land exploration, geology and meteorology.

It is anticipated that the shore station will be established on the MacRobertson Land coast, where several suitable sites are known. Two Auster aircraft will be taken on the *Kista Dan*. Shore operations will be undertaken with the aid of mechanical transport, 'weasels' and with dog-drawn sledges. The sledge dogs have been under training at Heard Island.

Robert G. Dovers, a son of George Dovers of the Queen Mary Land party of the Australasian Antarctic Expedition of 1911–14, is to be leader. For the work ahead he has already had good experience, as he was cartographer to the Heard Island party of occupation during 1948 and continued thereafter an active member of the expedition staff. Dovers, as observing officer for A.N.A.R.E. at the invitation of the commander of the French expedition, spent the year 1952 in Adelie Land gaining first-hand information in sledging operations.

Attached to Dovers's party during 1954 will be a French representative as observer.

The Planning Committee expects to extend greatly the scientific programme of the mainland station during subsequent years. Ice-cap seismic-sounding will then receive special attention.

OBITUARIES

Dr. W. A. R. Dillon-Weston

William Alastair Royal Dillon-Weston, chief plant pathologist in the eastern province of the National Agricultural Advisory Service, died in Cambridge on August 20, at the age of fifty-four. A West Countryman by birth, he was educated at Bristol Grammar School and St. Catherine's College, Cambridge, where, after gaining honours in Part I of the Natural Sciences Tripos, he took a diploma in agriculture in 1922. Shortly afterwards he was appointed by the University as one of the provincial advisory mycologists to the Ministry of Agriculture and Fisheries, stationed at the School of Agriculture, Cambridge. His subsequent working life of nearly thirty years was spent in serving the farming community of East Anglia, for although he left the University for the National Agricultural Advisory Service when it was established in 1946, his duties remained unchanged and his new station was but two miles from his old one. He took his M.A. in 1925 and a Ph.D. in 1929.

Dillon-Weston was a sensitive artist, full of stimulating and occasionally unusual ideas, kindly disposed to others, hospitable, and always ready to give a helping hand. Yet his restless impetuosity and sense of the dramatic, together with a tendency to brook no interference with his affairs, at times induced exasperation even among those who knew and admired him most. This conflict of qualities was reflected in his work and in his wide and changing interests. He combined research and advice in a manner that enhanced the value of both, and published nearly one hundred scientific and semi-popular articles on mycology and plant diseases, half of which were concerned with diseases of cereals and fungicidal treatment of cereal and other seeds. His early research was carried out on fruit tree diseases, notably apple scab; but he became increasingly interested in the rusts and smuts of cereals, particularly following on an exchange of posts for twelve months during 1930–31 with Dr. Craigie of the Dominion Rust Research Laboratory in Winnipeg. Shortly after his return from Canada he and Dr. J. R. Booer began an intensive study of the fungicidal action of mercury compounds. As a result of this and subsequent work, Dillon-Weston's name will long be linked with the advances made in fungicidal seed treatment in Britain. But he also investigated diseases of potato, sugar beet, clover, beans and other crops that came to his notice during his advisory work. He was interested in the theoretical as well as the strictly practical side, and his contributions ranged from the effect of ultra-violet radiation on fungus spores to the significance of 'black spot' in eggs.

His spare-time hobbies were many and varied, but mycology crept into most of them. When an enthusiastic airman, he studied the fungus flora of the upper air; later, as an expert glass-blower, he made many beautiful glass models of fungi; and as an artist he painted plant diseases, designed posters and film strips, directed films on potato blight and cereal seed disinfection and, with Ann Murray's assistance, issued pictorial life-cycles for many pathogenic fungi. In 1948 he published three popular booklets on diseases of farm and vegetable crops, and his book "The Plant in Health and Disease", written in conjunction with Dr. R. E. Taylor, appeared the same year. He was married and is survived by a widow and two children. W. C. Moore

---

Mr. T. Raymont

The death, in his eighty-ninth year, of Thomas Raymont removes one of the last survivors of that group of pioneers who at the turn of the century were establishing a livelier and more liberal conception of the training of teachers, in association—precarious at first—with the newer universities. Others among them were John Adams, and later Percy Nunn, at the London Day Training College, and J. W. Adamson at King's College in London, J. J. Findlay in Manchester, James Welton in Leeds and Mark Wright in Newcastle.

The greater part of Raymont's working life was concerned with teacher training, first for fifteen years as professor of education at Cardiff, and then for twenty-two years at Goldsmiths' College in New Cross, London. As vice-principal on the men's side and later as warden of the College, he had much to do with the development of that anomalous and adventurous institution, in which the so-called Day Training Department was advantageously part of a larger whole. Among his achievements was the establishment of general degree courses in arts and science for a proportion (about one-fifth) of the students in the Training Department, a number of members of the College staff being 'recognized teachers' of the University of London.

During his last year at Goldsmiths', he enjoyed the opportunity of a visit to America. When he relinquished the wardenship in 1927, he continued for a further eight years to act as educational adviser to the National Froebel Union and was chairman until 1937; he had been a governor of the Union for thirty years.

Raymont took a leading part in the emancipation of training colleges from the dead hand of nineteenth-century traditions, and was influential in the counsels of his colleagues. He was president of the Training College Association in 1928. He continued to the end to take an active interest in the Old Students' Association of Goldsmiths' College and was, as always, held in high esteem and affectionate remembrance by some thousands of his old students, both in London and in Cardiff.

His writings extended his influence, notably his "Principles of Education" (1904) and "The Use of the Bible in Education" (1911), both of which were widely used in their time. His later book, "Education" (1931), was a broad and mature survey of the field at large, steadily and as a whole, the wood rather than the trees.

Failing eyesight eventually led him to withdraw from London life to relative seclusion at St. Ives, but he continued to write book reviews in educational periodicals and until a few years ago he was a frequent contributor to *Nature*.

At the end of his long and fruitful life, it is fitting that Thomas Raymont's place should be recognized among the pioneers in educational expansion after the Act of 1902, and in particular in the liberalization of teacher training.

A. E. Dean

Prof. S. Parker Smith, C.B.E.

The genius of Stanley Parker Smith, who died suddenly at Perth on August 21, in his seventieth year, had two distinctly contrasting aspects: that of the practical electrical engineer and latterly that of the teacher and educationist.

During the earlier years of his career, his activities as designer of dynamo-electric machinery, particularly of large turbo-alternators and machines for special applications, earned for him a wide reputation. That he was invariably successful in his designs, particularly at a time of rapid expansion in the size of the units and in the complication of electric generating plant and motive power, can be attributed to a combination of knowledge, scientific and practical. This combination gave him almost complete self-confidence in technical matters. It was not unjustified. He once told me that, when his final revision of the design schedule for one of the largest turbo-alternators that had hitherto been made was finished, he was no longer particularly interested in it but turned his thoughts to another problem. When figures came through from the test-house, they showed a performance which was more often than otherwise an improvement upon the predictions upon which his firm's guarantee had been based.

Tenacity of purpose and singleness of aim were among Prof. Parker Smith's outstanding characteristics. His only hobby was his work. These attributes, in combination with exceptional academic ability, won for him a scholarship which took him from Grantham Grammar School to Armstrong College, Newcastle upon Tyne. He graduated B.Sc. in the University of Durham, with special distinction in electrical engineering. He was awarded in 1905 an 1851 Royal Exhibition research fellowship. This enabled him to complete his technical education at the Technische Hochschule in Karlsruhe, where he specialized in the study of dynamo-electric machine design under Dr. Arnold, who was possibly the outstanding authority on this subject. He was later awarded, by the University of Durham, the degree of M.Sc., which was followed by that of D.Sc. His most important contribution to this branch of science was his paper on the "Theory of Armature Windings" before the Institution of Electrical Engineers. This piece of work reflected the results of these years of intensive application. He is also represented by other papers, either wholly or in part authorship, on electric generators. He was also interested in electric traction, and a paper concerned with the calculation of the starting resistances for traction series motors was awarded a premium by the Institution of Electrical Engineers. About this time, a journey of investigation into Swiss and German practice was made and the results published.

After filling the positions of assistant designer with Siemens of Stafford (1907) and chief designer with the General Electric Co. (1909), in 1912 he accepted the post of lecturer in electrical design at the City and Guilds (Engineering) College of the Imperial College of Science and Technology, London, and afterwards became an assistant professor. He was appointed in 1923 professor of electrical engineering in the Royal Technical College, Glasgow, in succession to Prof. Magnus Maclean, who was the first holder of that title there. He resigned the chair in 1948 to become the organizer of the Staff College of the North of Scotland Hydro-Electric Board at Pitlochry in Perthshire.

During the time he occupied the chair in Glasgow, the Institution of Electrical Engineers accepted papers from him dealing with the cathode-ray oscillograph and with the domestic applications of electricity, and there were published the following text-books, which have continued into several editions: "Problems in Electrical Engineering", "The Electrical Equipment of Automobiles", electrical laboratory manuals on measurements and on machines, and an electrical engineering design-class manual.

As regards his record as teacher and educationist it may be recalled that four of his former students are now professors of electrical engineering, and the modernized teaching laboratories of the Electrical Engineering Department of the Royal Technical College at Glasgow also are witness to his work.

Prof. Parker Smith was always keenly interested in the activities and the well-being of the Institution of Electrical Engineers. He gave much time in helping to co-ordinate the functions of the Ministry of Education, the Scottish Education Department, and the Institution in bringing about the efficient and smooth working of the schemes for national certificates and diplomas. He had served as a member of council of the Institution and, in 1941, as vice-president. He was chairman of the Scottish Centre during 1939–41.

At the end of the Second World War, he received the award of C.B.E., in recognition of his services in connexion with the technical training of recruits to the Army, Navy and the Air Force at the Royal Technical College.

Prof. Parker Smith is survived by his widow, a son and a daughter.

F. E. Meade

TO SIR EDWARD APPLETON

On hearing his Presidential Address to the British Association, 1953

Within the hush'd and crowded hall, now gay
With learning's silken panoplied array,
We sit enrapt; companion'd, warm, secure
In a familiar world, serene, demure;
Our minds elsewhere, above the veil of night
Borne on imagination's thrusting flight
Through the unending, roofless vaults of space
Where galaxies pursue their timeless race
In distant majesty; about them spread
A seeming frozen silence, deathless, dead.
Did we possess your magic, we might hear
The voiceless ether murm'ring low and clear
A myriad soft whispers, mystic tone
Of outer worlds, the known and yet unknown.
How wise the mind that thus can apprehend
A universe too vast to have an end,
The ear its ghostly note detect, the hand
A new strange music of the spheres command.

Stanley Dumbell*

NEWS and VIEWS

British Association: President for 1954: Dr. E. D. Adrian, O.M., F.R.S.

Dr. E. D. Adrian has been elected president of the British Association for 1954 and will therefore preside over next year's annual meeting at Oxford. Dr. Adrian has been president of the Royal Society since 1950. His work, which has had such a profound effect on the biological sciences, was reviewed in *Nature* on his election as president of the Royal Society (*Nature*, 166, 978; 1950). Much of his scientific research was carried out while he was Foulerton professor of the Royal Society during 1929–37 and later professor of physiology in the University of Cambridge during 1937–51. He holds the Baly Medal of the Royal College of Physicians, a Royal and the Copley Medals of the Royal Society and the Gold Medal of the Royal Society of Medicine. In 1932 he was awarded the Nobel Prize for Medicine, and in 1942 he received the Order of Merit. Since 1951, Dr. Adrian has been Master of Trinity College, Cambridge.

Downe House

Downe House, Kent, the national memorial to Charles Darwin, where for forty years Darwin lived and where he wrote his "Origin of Species", has been transferred from the custody of the British Association to that of the Royal College of Surgeons.

Technology and Professional Work

Some points raised by Lieut.-Colonel S. M. K. Mallick's address, "Medicine—a Technology or a Profession", at the plenary session on August 24 of the First World Conference on Medical Education are of interest in the wider context of current discussion in Great Britain on higher technological education generally. Accepting the definition of a profession as implying an occupation in which one professes to be skilled and which one adopts as a means of living, Col. Mallick thought that there are still good reasons for restricting the word 'profession' to the three vocations of divinity, law and medicine. He defined technology as a systematized or scientific study of the practical or industrial arts, while medicine he claimed is a specialized knowledge the practice of which is concerned with disease and the advancement of health. Despite this rather controversial restriction of the term 'profession' and his failure to probe deeply enough into the meaning of technology, which he does not distinguish at all clearly from a technique, Col. Mallick's concern that through the mass-production of immature specialists, aided by socialization, the profession may be converted into a technology and the medical man become merely a high-class technician, has implications for the planning of higher technological education and especially for those who insist on the importance of an adequate basis of general education. The danger in medicine is that the specialized studies which are so readily encouraged by current tendencies will swamp the basic general education that a university discipline, such as medical education, is calculated to impart. A system which is more than vocational training must have a relevance to life in general, and though technical education is an indispensable foundation, education in the sense of the development of the power to form judgments becomes possible only after techniques have been mastered. Col. Mallick believes that the danger in medicine would be averted by the revival of the general physician and the general surgeon on better-organized lines, and by recognizing the difference between profession and technology and re-establishing the pre-eminence of the professional aspect and tradition.

Science and Productivity in Britain

In a debate on science and productivity in the House of Commons on July 20, the Parliamentary Secretary to the House of Commons, Mr. Hugh Molson, referring to the recommendation in the sixth report of the Advisory Council for Scientific Policy regarding the increased use of development contracts, said that the Ministry of Fuel and Power has already granted contracts for developing gas turbines run on peat and on coal, while several contracts have been granted for developing the large heat pump made for heating and cooling the Royal Festival Hall. Mr. Molson said that the Department of Scientific and Industrial Research is also exploring the practicability of development through the research associations, and referred to collaboration between the Road Research Laboratory, the British Road Tar Association and the North Thames Gas Board in the preparation of a special type of tar for road-surfacing, and between the Building Research Station and the British Electricity Authority in developing the manufacture of bricks from the ash of power stations. Mr. Molson also reaffirmed the Government's intention to build a science centre in London and said that the site on the South Bank is still reserved for the purpose.

---

* Registrar, University of Liverpool, and Joint Local Hon. Secretary of the British Association Meeting at Liverpool, 1953.

Little else of fresh interest emerged in the debate. Sir William Darling pointed out that the most effective industrial research organizations are created by industrial firms themselves, and there is some general recognition of the dangers of relying on a government organization, even of the type of the National Research Development Corporation, for development work; there is also the vital importance of good industrial relations in securing the effective co-operation on which efficient production depends. Equally, he added, it is recognized that the practice of indiscriminately denigrating business enterprise and management is not conducive to good relations and co-operation. Mr. A. Allen made a point that is now exercising men of science when he referred to the other arduous duties of the Lord President of the Council and urged that there should be a senior minister giving undivided attention to the scientific responsibilities and interests of the Lord President. Mr. W. Shepherd pressed for greater use of consultants in industry.

Education and the Oil Industry

THE world demand for the products of petroleum has more than doubled over the past fifteen years. It may well double again in the next fifteen years and, if so, there will be need for an increasing number of men who, by combining ability, technical knowledge and experience, can fill administrative posts of all kinds. The petroleum industry was among the first to seek the help of the universities in meeting its need for technical and administrative staff, in promoting academic studies in the applied sciences and in furthering education and training within its own organization. This has been particularly true of the Shell Organization which, with its associates in the Royal Dutch/Shell Group of oil companies, to-day operates in more than fifteen countries and employs a quarter of a million persons ("Venture in Education". Pp. 8. London: Shell Petroleum Co., Ltd., 1953). The Organization is faced with many educational problems in many lands and its general policy has had to be adapted not only to the industry but also to the community it serves. For a long time the universities have been looked to for men qualified for the technical side of the business. It has also been realized that the intellectual discipline of university training was no less valuable on the commercial and administrative sides than on the technical, and in particular that the Group's overseas marketing organization offered scope and opportunity to the arts graduate. A record of the activities of the Shell Group has been set down in a publication called "Venture in Education", which also indicates the financial support which the Organization has given to the universities. So long ago as 1912, for example, a donation was made to the University of Cambridge for a readership in physical chemistry, and this was followed in 1919 by a gift of £50,000 towards the establishment at Cambridge of the physical chemistry laboratory. Recent donations have totalled well over half a million pounds, while each year the Organization is spending a total of approximately £275,000 on its own educational activities.

City and Guilds of London Institute

ON the threshold of its seventy-fifth anniversary, the City and Guilds of London Institute finds itself in a critical and challenging position (City and Guilds of London Institute. Report of the Council for the Year 1952. Pp. 52. London: City and Guilds of London Institute, 1953). There is little doubt that the national importance of its work in technical education is appreciated, as is shown by the continued call for its syllabuses in established and new industrial fields and for its advisory services in educational matters of a more general and far-reaching nature. The critical point has been reached because the available resources of the City of London Corporation and Livery Companies can no longer maintain, let alone expand, the work of the Institute. The problem of accommodation for the Department of Technology is seriously hampering its work; suitable accommodation conveniently located and on one site would ease administration and lead to appreciable economies. In view of the increasing amount of work of the Department of Technology, this is a matter which is causing grave concern to the Council of the Institute. Since the War, the number of candidates taking examinations under the ægis of the Department of Technology has more than doubled. There have also been sixty-five major revisions, and thirty-one completely new subjects have been introduced. These figures are all the more impressive when it is realized that in many cases a subject may, in fact, include two or three independent schemes of syllabuses and related examinations. The need to balance claims of the development of a large number of new projects against the revision of existing subjects is a constant problem for the Department of Technology. At present, twenty subjects are being scrutinized and will shortly be completely revised. At the same time, many new subjects are in preparation.

Impact of Industry on the Worker

IN an imaginative but well-authenticated article, Nigel Balchin, the well-known psychologist and author, examines the way in which the growth of industry has affected the outlook and philosophy of those who work in large or small industrial undertakings (*J. Inst. Personnel Management*, June 1953). A comparison is made between the life of the agricultural worker and of the individual whose working life is confined to the factory, and Balchin concludes that the impact of industry upon the worker has been to destroy the simple and direct significance of work done and hence to sever the mental link between 'work' and life. In these circumstances 'work' is liable to become something which has no logic or point in itself. The impact of the huge and complicated industry structure on the worker has been to confuse the mind as to his real desires and requirements and to leave him with a vague impression that man exists for industry rather than *vice versa*.

Cambridge University Educational Film Council

THE sixth report of the Cambridge University Educational Film Council contains a description of experiments which have been made in the use of films for teaching history (Cambridge University Educational Film Council. Sixth Report, March 1953. Pp. 8. Cambridge, 1953). In collaboration with the Cambridge Branch of the Historical Association, a series of feature films have been shown to complement 'outline courses' in medieval and modern history of the Faculty of History. The films shown included "Alexander Nevsky", "Der Alte und Junge König" and "M. Vincent". In collaboration with the same Association the Film Council also arranged a film demonstration at which the films "Stone Age Tools", "Paridiso-Perduto", "Transfer of Power", and "Edwardian Newsreel" were shown. Film sessions have also been arranged for students of economics, Slavonic studies, archæology, anthropology, geography, engineering and zoology. Considerable use of films is made in the Department of Anatomy, where films for teaching purposes have been made. A useful teaching film showing stream erosion in a laboratory model has been completed in the Department of Geography. The use of cinematography in research continues in a number of university departments, including those of engineering, geography, geodesy and geophysics, and experimental psychology. In the Department of Anatomy, films showing the growth of nerve fibres and the reaction of chemotherapeutic compounds on living cells have been made; in the Cavendish Laboratory a new version of the bubble model film has been prepared.

Three-Dimensional Films

It is curious that the widespread interest in three-dimensional films should have been stimulated by the appearance of a two-dimensional panoramic system—'Cinerama'—followed closely by the announcement of a similar system yet to come—'Cinemascope'. Although both are spectacular, neither method is truly stereoscopic, the specious illusion of some depth attained being dependent upon wide-angle peripheral vision and upon the slightly different images seen by each eye, both effects being conferred by a curved screen. Other older systems which rely upon a truly three-dimensional presentation have benefited by this publicity in being brought more into public awareness. Before a film can be called '3-*D*' it must be truly stereoscopic. For this, it is essential that each of the viewing eyes shall receive a dissimilar picture from the other—the so-called 'disparate' images that are seen in real life by two separated eyes. In consequence, whatever the methods of projecting pictures upon the screen may be, it is essential that there should be differentiation as between the two eyes, either at the eyes or at the screen. Systems using the first of these methods, where the required discrimination takes place at the eyes, are at the moment more successful and are commercially therefore more important. The possibilities of three-dimensional films are discussed by H. Dewhirst in a recent issue of *Science and Film*.

Limits of the Oceans and Seas

The third edition of "Limits of Oceans and Seas" has been published by the International Hydrographic Bureau, Monte Carlo (pp. 38; 1953; n.p.), and consists of thirty-eight pages of text and three large diagrams, giving the position and extent of the seas. The limits as described in the text and shown in the diagrams are solely for the convenience of national hydrographic offices in compiling notices to mariners and for other practical reasons; they have no relation to physical considerations and, of course, are of no political significance. The Antarctic, or Southern Ocean, is now omitted on the plea that this body of water has no well-defined limits to the north, but rather a seasonal variation. The southern limits of the other oceans are therefore extended to the Antarctic continent, and the various Antarctic seas, such as Ross, Weddell and Bellingshausen, are omitted. Straits joining two seas have been allotted to one of them. Meridians, parallels and rhumb lines have been used so far as possible for the limits of seas. The extent of the great oceans, including the Arctic Ocean, excludes the seas lying within each of them, this being mainly for practical purposes.

Men of the Trees

The summer issue of the journal of the Society of the Men of the Trees contains an account by Mr. Richard St. Barbe Baker of the expedition which he led last year to survey desert areas in Africa and to advise on means of combating erosion by afforestation (**17**, No. 1). To publicize and finance the "green front campaign against the desert", stamps have been produced showing a 'lone tree' in the middle of the Sahara. This tree stands six hundred miles from others in the middle of the desert, although the forest which was once there had disappeared because of drought or had been obliterated by sand storms. With the money collected from the sale of the stamps it is hoped to complete the desert survey and to purchase tree seeds and start tree nurseries in positions where they are most urgently needed. The journal also contains articles on the New Forest by J. Brambell Hill, the Worcester Beacon by E. R. Gordon, Cranford Park by A. Leonard Summers, the third in a series of articles on the biological task of forestry by Henry Baldwin, and a fine lyrical poem on elms by Leonora Lockhart.

Mutagenic Possibilities of Phosphorus-32

The occurrence and utility of bud sports in fruit trees have been discussed by W. R. Stanton and W. K. Sinclair (*J. Exp. Bot.*, **4**, 10, 78; 1953) and the merits of various mutagenic agents compared. These authors suggest that phosphorus-32 may prove a suitable mutagen in the production of fruit-tree mutations. In particular, experiments are described on the uptake and distribution of phosphorus-32 by plums. It is shown that the concentration of phosphorus-32 in buds may reach a level at which mutagenic effects are likely to be induced, but that at such concentrations there is little evidence of macroscopic injury. The method which is described—based on the culture of young trees in sand plus nutrients—appears to be suitable for fruit trees.

Micro-organisms maintained in Australian Institutes

The Commonwealth Scientific and Industrial Research Organization of Australia has issued a booklet entitled "Directory and Catalogue of Micro-organisms maintained in Australia", which lists the micro-organisms held as type cultures in the biological institutes of Australia (pp. 74; Melbourne: C.S.I.R.O., 1952). This work has been done to implement a recommendation of the British Commonwealth specialist conference on culture collections of micro-organisms, which was held in London during August 1947, that a directory of important culture collections in the Commonwealth should be prepared. At present there is no centralized collection in Australia. The Australian "Directory" embodies information submitted by forty-two institutions and lists several hundred species of bacteria and fungi, some seven species of protozoa, some fifty strains of yeasts, fifty-seven strains of bacteriophages, and twenty-nine strains of viruses. The strains are classified into those authenticated by other national collections of type cultures, or by Australian specialists, and those cultures the authenticity of which cannot be guaranteed. The "Directory" should admirably fulfil its function of informing scientific workers in Australia and in neighbouring countries of the biological material that is readily available to them, and of advertising to men of science elsewhere the extent of Australian collections.

Kodaikanal Observatory during the Past Fifty Years

A SURVEY of the work of the Kodaikanal Observatory during the past fifty years, from the days of Prof. C. Michie Smith, the first director, up to the present time, is contained in a small booklet entitled "Kodaikanal Observatory 1901–51", issued by the Indian Meteorological Office (pp. 44+12 plates. Delhi: Manager of Publications, 1952; 1 rupee). A considerable amount of the publication is devoted to an account of the work of Evershed, who became director in 1911 after four years as assistant director, and of Royds, who joined as assistant director in the year in which Evershed became director. It is pointed out that the period of sixteen years that Evershed spent at Kodaikanal was marked by great activity, and his and Royds's researches during this time brought Kodaikanal to the front rank among astrophysical observatories. Besides a brief historical outline of the establishment and development of the Solar Physics Observatory at Kodaikanal in 1899, which was derived from the Madras Observatory started in 1792 by the East India Company, the publication describes the instrumental equipment and observational work carried out by the sixteen instruments and five different spectrographs. The account of the work includes sections on the following subjects, among others: discovery of radial motion in sunspots; memoirs on sunspot spectra and prominences; sun-arc displacements—pressure in the reversing layer; Venus spectra; spectroscopic studies; studies on sunspots and prominences; study of Hα dark markings; and prominences and radiation pressure. Supplies of photoheliograms have been sent to the Royal Greenwich Observatory almost from the beginning, and since 1906 exchanges of spectroheliograms have been made with the Solar Physics Observatory, Cambridge. Future developments depend on the financial aid which can be obtained, as contributions in practical and observational work are handicapped from lack of instrumental equipment. As one instance, a really large solar spectrograph with an adequately powerful coelostat and other accessories, and a Lyot coronagraph are badly needed. Although the Government of India appointed a Standing Advisory Board for Astronomy and Astrophysics in 1948, and a meeting was held in April 1949 as a result of which recommendations were made to the Government, very little had been done up to the time of writing. It is to be hoped that the present director, Dr. A. K. Das, will be able to secure the necessary funds to maintain and even enhance the excellent reputation of this Observatory. Just of late a few items have received attention, and it is very satisfactory to know that the ionospheric laboratory has been completed and the ionosphere recorder installed.

Memoirs of the Society for Endocrinology

THE Society for Endocrinology is proposing to publish a series of memoirs recording the proceedings of conferences on endocrinological subjects. The first memoir, on the thyroid gland, has recently appeared and contains papers read at a conference held in London on February 25, which was organized by the Society jointly with the Endocrinological Section of the Royal Society of Medicine (pp. 48+4 plates; 3s. to members, 5s. to non-members). The second, which reports a recent conference on the determination of adrenocortical steroids and their metabolites, is in the course of preparation and will be ready shortly. By means of this new venture the Society hopes to effect speedy publication in convenient form, and at a low cost, of papers on topics undergoing rapid change, and, to this end, typolith printing has been used in spite of its æsthetic shortcomings. That the Society has been successful in its main object of rapid publication is apparent from the fact that the memoir on the thyroid gland has appeared only four months after the conference, a notable achievement under present conditions. The memoirs can be obtained by non-members of the Society through any bookseller or direct from Pitmans Press, Parker Street, London, W.C.2.

Medical Research Council: New Members

BY an Order of the Committee of Privy Council for Medical Research, made after consultation with the Medical Research Council and with the president of the Royal Society, Prof. Robert Platt, professor of medicine in the University of Manchester, and Prof. Edward T. C. Spooner, professor of bacteriology and immunology in the London School of Hygiene and Tropical Medicine, have been appointed to be members of the Medical Research Council as from October 1, 1953.

Welded Steel Structures

A JOINT committee appointed by the Ministry of Works, the Institution of Civil Engineers and the Institution of Structural Engineers, with the support of the Admiralty, War Office, Ministry of Supply, Ministry of Transport and Department of Scientific and Industrial Research, is organizing a conference, the purpose of which is to review present knowledge and outstanding problems in the design, fabrication and erection of welded steel structures. The conference will be held at the Institution of Civil Engineers, Great George Street, London, S.W.1, during November 23–27. Eleven topics have been chosen for discussion, for each of which a special review paper has been prepared; the papers will be circulated beforehand so that most of the time at the conference can be used for discussion. The conference is open to all interested in the subject. Application forms for membership and all further information can be obtained from the Joint Honorary Secretaries, Conference on Welded Structures, Institution of Civil Engineers, Great George Street, London, S.W.1.

Shell Petroleum Co. Awards

POSTGRADUATE scholarship awards have been made by the Shell Petroleum Co., Ltd., to the following overseas students to enable them to work in British universities: E. A. Parkes, of the University of Tasmania (London), and A. D. Buckingham, of the University of Sydney (Cambridge); M. H. Panckhurst, of Canterbury University College, N.Z. (Oxford), and J. H. Percy, of Auckland University College (Cambridge); M. J. Stephen, of the University of the Witwatersrand (Oxford), and W. A. Little, of Rhodes University College (Glasgow).

STRUCTURE OF THE ATOMIC NUCLEUS

ABOUT three hundred nuclear physicists, a hundred and twenty of them from overseas, met at the University of Birmingham during July 13–18 for discussions on nuclear structure. At each session, an opening speaker surveyed some portion of the field: his introduction was followed by contributions from those who had new information or who took other points of view. Much of the value of such a conference lies in the debating of divergent opinions or apparently contradictory experimental facts, but a report after the style of *Hansard* is not possible. The following account, covering only a few of the topics actually discussed, is intended to pick out some of the points of liveliest interest.

In several of the sessions the question of nuclear models was raised. In particular, this referred to the suitability of the 'shell model', as opposed to the 'liquid drop' model. The first treats the nucleus, as is usual in the case of the atom, as an assembly of individual particles, moving independently in a common field of force. For the past few years considerable success has been obtained from the use of this model, provided one assumes that there exists for each particle a strong interaction between its spin and its orbital angular momentum. B. H. Flowers (Harwell) summed up this picture in one of the opening talks and showed that, by making use of the correct alignment of the orbits of different particles when there is more than one particle outside a closed shell, one can account for the behaviour of magnetic moments and quadrupole moments in cases which had previously presented difficulty. Many other successes of the shell model, relating also to nuclear reactions, were referred to in the discussion.

On the other hand, it was stressed by A. Bohr (Copenhagen) that an approach starting from a collective motion of many particles also finds a good deal of support from direct evidence. He assumes that the potential field acting on all the particles has a fairly sharply defined surface which may alter its shape as a result of the motion of the particles, and which therefore represents a set of degrees of freedom of the system. Since this surface is coupled with the motion of each particle inside it, it provides an indirect means of connecting the motion of different particles.

One particular piece of evidence favouring this 'liquid drop' model is the existence of 'rotational' states in certain nuclei. To take the simplest case, an even–even nucleus with angular momentum zero in its ground-state, often is found to have excited states of angular momenta 2, 4 . . ., the energy of excitation being proportional to $J(J + 1)$, where J is the angular momentum. The factor of proportionality defines an effective moment of inertia, and this is found to be much larger than that for a single nucleon in an orbit the size of a nucleus, but much smaller than that for the whole nucleus considered as a rigid body. According to the Bohr theory, these states are to be understood not as a rotation of the nucleus as a whole but as an irrotational mode of motion in which the shape of the external surface revolves about its centre. As this model predicts, the transitions between such levels are associated with very large electric quadrupole moments which would not easily be explained in other ways. T. Huus (Copenhagen) described recently published experiments in which excited states, interpreted as rotational levels, are produced by the electric field of protons passing close to nuclei but not actually colliding.

In one sense the liquid drop model is a different extreme to the shell model, and the use of these different pictures in itself does not necessarily constitute a contradiction. In particular, the liquid drop model does not allow for the peculiar features arising from the closing of shells and should be most satisfactory well away from the closed-shell nuclei (magic numbers), whereas the shell model becomes prohibitively complicated in that region and allows the most precise predictions near the closed shells.

However, differences of opinion arise when one has to decide which of the two pictures is appropriate in any particular problem, and such points led to a lively discussion. The questions were not, of course, finally resolved, but the discussions gave all participants a rather clearer idea of the unsolved problems.

Another question about models which figured prominently in the discussion was the proper description for a nucleus in interaction with a fast neutron or proton. H. H. Barschall (Wisconsin) reported very extensive and interesting results about the scattering of neutrons in many nuclei, both as regards energy dependence and angular distribution, and this seems to agree remarkably well with a model proposed by Weisskopf in which the nucleus is treated as a sphere with a constant refractive index and absorption coefficient—a 'clouded crystal ball'—though the absorption coefficient used to fit the curves is surprisingly small.

Several different methods of estimating the radius of a nucleus were mentioned, the most extensive work being reported by R. Hofstadter (Stanford) on the scattering of 150-MeV. electrons by nuclei. These curves are interpreted directly as diffraction patterns. They would indicate an electric density distribution in the nucleus with a fairly strong maximum in the middle and a gradual decay rather than the usual picture of a uniform density with a sharply defined boundary. However, the distortion of the electron wave function by the electric field of the nucleus is large enough to throw doubt on the simple diffraction theory, and more work will have to be done to be sure of the interpretation of the experiments. The energy difference between the $2p$- and $1s$-levels of μ-mesons near a nucleus also tends to indicate that the generally accepted formula for the nuclear radius may not be reliable.

In considering most nuclear processes, it is proper to think of a nucleus as an isolated system, but one session of the conference centred around instances where the surrounding electrons, or even neighbouring atoms, are of major importance. Conversion of nuclear excitation energy through interaction with the atomic K, L, M . . . shells is a stock example; so also is the capture of an orbital electron by a nucleus. In addition to these, there were discussions of the directional correlations of successive radiations from a single atom. The anisotropy of the second radiation with respect to the direction of the first may be upset by a change of orientation of the nucleus while in the intermediate state. E. Heer (Zurich) described the effect of an external magnetic field on correlation between successive transitions in cadmium-111 (the product of the β-decay of indium-111), from which the magnetic moment of the first excited state could be deduced. The anisotropy in the absence of an external field depends upon the crystalline state of the source; for a polycrystalline indium source, it shows a maximum value of 20 per cent at the melting point. Experiments with single (non-cubic) crystals showed a dependence of the observed anisotropy upon the orientation of the counters with respect to the crystal axes.

Other topics involving atomic processes were the elastic scattering of gamma-rays, in which scattering by bound electrons is coherent with nuclear scattering and the orientation of radioactive nuclei by magnetic fields at low temperatures, which has been achieved with elements that form Tutton salts.

In sessions devoted to experimental techniques, reports were given by D. Walker and J. H. Fremlin (Birmingham) of the processes by which multiply-charged ions (for example, ${}^{14}\mathrm{N}^{++}$) can be accelerated in a cyclotron and of the types of nuclear reaction that such relatively heavy nuclei produce. Particular interest was shown in an impromptu description given by R. Birge (Berkeley) of the bubble-chamber experiments initiated by Glaser at Michigan, in which ionizing particles cause ebullition in a superheated liquid.

SECOND INTERNATIONAL CONGRESS ON RHEOLOGY

THE Second International Congress on Rheology was held in Oxford during July 26–31 and was attended by some 245 rheologists accompanied by about fifty visitors. The proceedings commenced with an address on "Rheology for Mathematicians", given by the president of the Congress, Sir Geoffrey Taylor, who discussed various way in which mathematicians can help rheologists and the attitude of practical rheologists to the pure mathematician.

The technical programme of the Congress consisted of six invited lectures as well as a number of sectional meetings run in parallel. Nearly half of the forty-nine contributed papers dealt with properties of high polymers, and these provided the subject-matter for Section *A* for the whole of the Congress. A short (half-day) Section *C* was concerned with problems of lubrication, all other contributions being grouped into a miscellaneous Section *B*.

In drawing up the programme, the aim of the organizing committee had been to cover the extended field of "the study of the deformation and flow of matter" as widely as possible. The subjects of the invited lectures illustrate this policy: *sur l'effet éléctrovisqueux* (Mme. A. Dobry-Duclaux, Paris); rheological problems in the fabrication of plastics (Dr. R. S. Spencer, Midland, Mich.); rheology and applied mechanics (Dr. R. N. J. Saal, Amsterdam); rheological behaviour and the molecular jumping mechanism (Prof. F. H. Muller, Marburg); water association and hydrogels (Mr. E. Forslind, Stockholm); and biological problems for the rheologist (Dr. P. Eggleton, Edinburgh). As well as many papers on plastics and high polymers generally, sectional papers covered a wide range of materials—for example, clays, metals, gelatine gels, flour doughs, diamonds, greases, bitumens and protoplasm. Discussions ranged from methods of viscometry to the study of chronic bronchitis in man and the diagnosis of pregnancy in the cow. Papers were read, and discussions took place, in English, French and German.

Most of the papers were circulated as preprints before the meeting opened; all of them, together with summaries of the discussions which followed, will be published in book form by Butterworth's Publications, Ltd., London, and will appear, it is hoped, within about six months. In conjunction with the Congress there was a small exhibition of commercially available rheological apparatus, and an Oxford bookseller also arranged a special display of rheological books.

There were three evening meetings. At the first of these, a number of technical films was shown, including one illustrating Sir Geoffrey Taylor's own investigations on the dragging of anchors. Another evening was devoted to a discussion on international organization of rheology, at which the International Union of Pure and Applied Physics was represented by its president, Prof. N. F. Mott (Bristol), the International Union of Chemistry by Mme. A. Dobry-Duclaux (Paris) and that of Theoretical and Applied Mechanics by Prof. J. M. Burgers (Delft). It was decided to form an International Committee on Rheology consisting initially of one representative each from all national groups devoted solely to the study of rheology, with power to co-opt individual rheologists from countries where no such groups as yet exist. The membership of the committee is temporary, until the national societies can elect their own representatives. Later in the Congress, the representatives of France (Prof. H. Weiss), Germany (Prof. F. H. Muller), Great Britain (Mr. A. G. Ward), Netherlands (Dr. R. N. J. Saal) and United States (Dr. R. S. Spencer) met under the chairmanship of Mr. Ward, and co-opted Prof. B. Gross (Brazil), Prof. M. Reiner (Israel) and Prof. A. Peterlin (Yugoslavia). It was resolved also to send invitations to rheologists in India, Japan and the Scandinavian countries. The purposes of the Committee were laid down as follows: "(1) To be a permanent body for organizing future International Congresses on Rheology, (2) to encourage new national organizations for the study of rheology, and (3) to act as co-ordinating body in other international co-operations in the field of rheology". Dr. R. N. J. Saal (Amsterdam) is acting as temporary secretary.

A third evening was devoted to a discussion on nomenclature and symbols. A number of reports formed a basis for the discussion, including that by Prof. J. M. Burgers and Dr. G. W. Scott Blair, published in 1949 under the auspices of the now defunct Joint Committee on Rheology. Dr. H. Leaderman (Washington, D.C.) reported on the still tentative but valuable "proposals for nomenclature for linear visco-elastic behavior" put forward by the Committee on Nomenclature of the (American) Society of Rheology. Following the discussion, certain recommendations were sent to Dr. Saal as secretary of the new International Committee.

At the Congress dinner, held in the Hall of Christ Church, Sir Ben Lockspeiser, as guest of honour, in reply to the toast of "The Guests", proposed by the president, summarized the history of the British Society of Rheology and recalled the First Congress held in Scheveningen in 1948. Dr. R. S. Spencer, president of the American Society, proposed "International Rheology", to which Mme. Dobry-Duclaux replied in French.

The Congress was closed by Prof. A. Peterlin (Yugoslavia), who expressed the gratitude of overseas rheologists to their British colleagues who had organized the Congress. Under the auspices of the newly formed International Committee, it is hoped that other equally pleasant and profitable congresses will be held in future years.

G. W. SCOTT BLAIR

RAT BEHAVIOUR

PERHAPS the rat, more than any other animal, is to be found in the laboratories of many of the biological sciences, and it was therefore a good subject for a miscellany of papers at the symposium on "Rat Behaviour", held at Birkbeck College (University of London), during July 9–10, by the Association for the Study of Animal Behaviour.

Topics covered at this symposium were: hormones and maturation, food-selection, convulsions, perceptual functions, stereotype behaviour and learning. J. T. Eayrs (Birmingham), in a paper entitled "Hormones and Central Nervous Maturation", described investigations of the functional relationships between endocrine and central nervous systems. In particular, the secretions of gonads and thyroid were varied, by ablation or injections, and behavioural concomitants studied by means of an ingenious battery of tests. In some cases, histological studies of the brain were also made; changes in bifurcations and lengths of dendrites, as well as vascularity, were observed. Analysis of results suggested that the functioning of certain postural co-ordinating centres is accelerated by the secretion of androgens, and that this facilitatory process may extend to higher forms of behaviour. With regard to thyroid functions, it has been widely accepted that the cerebral changes associated with untreated cretinism in man are irreversible. However, rat experiments still in progress furnish evidence that replacement therapy may restore both behaviour and cortical structure to normal. Experiments with the steroid hormones support in general the hypothesis that the hormone acts on a nervous mechanism which is genetically determined and which develops independently of the endocrine organ with which it is later associated. Thyroid hormone, on the other hand, although it may facilitate the functioning of quite specific centres, exerts an influence on central nervous maturation (there is some evidence that androgens do also); it is not known whether this is a primary or secondary effect.

S. A. Barnett (Glasgow) presented a paper entitled "Problems of Food Selection in Rats", in which he classified food preferences according to whether they were common to the species (for example, in the wild rat, preference for sweet foods, avoidance of aniseed oil) or dependent on the past history of the individual. Of the latter kind, experiments have shown that albino rats can usually select the nutritionally better of two foods, though past familiarity with a given food may result in its still being chosen in the presence of a better food. The development of poison shyness in wild rats was likened to the development of choices of beneficial foods. Food preferences, which are probably short-lived, may be induced by other members of the colony; for example, an unusual food may be brought to the nest by one rat and consumed by the others also. The choice of foods by young rats may to some extent be influenced by their tendency to orientate themselves on the mother; however, there is no evidence for detailed imitation. The rat's highly developed tendency to explore its environment and sample everything in it, together with its capacity for associative learning, leads to the consumption of a great diversity of foods. Dr. Barnett showed a film of experiments made on food preferences which had been lent by the Infestation Control Division of the Ministry of Agriculture and Fisheries.

M. R. A. Chance (Birmingham) read a paper on "Convulsions in the Normal Behaviour of Rodents". The experiments reported were done mainly on mice; but there was sufficient evidence to indicate that the results might be generalized to rats. When stimuli produce convulsions in a mouse, the amount of glycogen in the brain increases. Rises in blood-sugar and injection of the anti-insulin hormone also may increase the amount of glycogen but not to the extent produced by convulsions. It was thought, then, that large increases of glycogen in the brain might indicate behaviour of a convulsive nature. These increases have been found to occur with behaviour usually considered normal. For example, the falling posture adopted by a mouse when support is removed can be shown to protect it against hæmorrhage resulting from concussion at the end of the fall. The posture occurs within a fraction of a second, and so does the glycogen increment. The rigidity of the limbs and trunk suggests that many muscles participate in maintaining the posture, and that, therefore, not only a maximal rate of discharge, but multimotorneuronal discharge may be involved. It was considered, therefore, that audiogenic hyperexcitement, including convulsions, which are usually considered abnormal, should be thought of as part of the animal's normal repertoire. It was suggested that such behaviour is a type of emergency reaction appropriate to a situation in which there is an absence of clues for a more differentiated response. In these circumstances, *Peromyscus* exhibits an excessive flight reaction followed by aggressive saltation and the sequence ends in cataleptic postures. The volume of evidence already brought forward to show that audiogenic seizures are likely to occur in animals with pathological conditions is not evidence in itself that this mode of discharge is always pathological; the discharge may be thought of instead as indicating a release of the lower motor centres from cortical integration.

The three remaining papers came from psychological laboratories. I. M. L. Hunter (Oxford) summarized what is known of the role vision takes in rat behaviour. By means of extirpation experiments, it has been shown that vision is the dominant sense when a rat is learning an elevated maze, olfaction being secondary. Normal rats use both intra-maze and extra-maze visual stimuli; but the latter are especially important. In general, it appears that the rat's visual world is dominated by the more distant and more stable features of the environment. Hence in the enclosed maze, vision seems to be less important, olfaction and taction being dominant. Specially designed apparatus has been used for showing that rats are able to react to wave-length properties of red light, and that they are able to discriminate brightness, pattern and size. However, certain environmental features are more readily reacted to than others, and this has led to the suggestion that discrimination learning involves trying out a succession of 'hypotheses' until the correct one is found, that is, involves reacting now to this selected set of characteristics, now to that, learning meanwhile nothing about those characteristics 'not attended to'. Experiments have discredited this view; in general, it seems to be the entire discrimination situation to which the rat reacts. In brightness and in size discriminations, the rat may react to either the absolute or the relational features of the stimuli. It will react to relational features particularly if the stimuli resemble each other, or as a result of practice. The mechanism is not understood. It was concluded that the visual system functions most efficiently in spatial orientation, that is, in the discrimination of distances and directions.

R. H. J. Watson (London) read a paper on "Stereotype Behaviour in the Rat". Such behaviour is one of many kinds often called abnormal which are conveniently studied in the rat. Mr. Watson considered in detail the difficulties encountered in arriving at criteria for normality and abnormality of behaviour. He considered in particular the suggestion made by Maier that behaviour should be considered normal if it were predictable from learning theory, abnormal otherwise. Using this criterion, Maier claimed that stereotype behaviour was abnormal, instigated by frustration resulting from presenting the rats with an insoluble problem. Mr. Watson reported experiments in which a more complex insoluble problem was used and in which a more complex stereotyping resulted. The analysis of the results indicates that, both in the insoluble problem and in a subsequent soluble problem, the behaviour conformed on a number of criteria to that which would be predicted from conventional learning theory. The results also suggested that such stereotypes would be self-perpetuating.

H. B. M. Hurwitz (London) read a paper, "Response Patterns in the Rat", which was also concerned with the predictive value of learning theory. In learning theories, it is commonly assumed that the strength of a response is a function of habit strength together with drive strength. The favourite experimental device for investigating the roles of these two factors is the Skinner box, in which rats learn to depress a lever to obtain delivery of food in a food trough. When the habit has been learnt, food is withheld and a count made of the number of lever-pressings produced before the habit is extinguished. Data obtained in this way are of basic importance to the theories of Hull and Skinner, for example. Mr. Hurwitz reported experiments using a modified Skinner box (which he demonstrated) with which the temporal and serial patterning of responses (both at the food trough and the lever) could be observed. Analysis of results suggested that the postulation of a secondary drive, frustration, could best explain the behaviour of the rat during extinction of the habit. Evidence for this would not have been forthcoming if conventional methods of analysing responses had been used.

General discussions on the papers were introduced by Profs. R. W. Russell (London) and W. S. Verplanck (Harvard). There were detailed discussions on methodology of the individual researches reported; more general topics covered included behavioural differences between various strains of rats, the use of the concept 'abnormal', and the predictive value of learning theories.

B. M. Foss

CAREERS IN CHEMICAL ENGINEERING

An unexpected occurrence during the past few years has been the large decline in the numbers of men seeking admission to the universities for training as engineers, a decline noted not only in Britain but also to an even greater extent in the United States. Simultaneously, committee after committee has urged the need for more engineers in general, and chemical engineers in particular. Extensive training schemes will obviously be of little value unless the numbers of those willing to be trained can be greatly increased, and thus the issue by the Institution of Chemical Engineers of a small brochure entitled "Careers in Chemical Engineering" is most opportune (pp. 12+4 plates. Inst. Chem. Eng., 56 Victoria Street, London, S.W.1, 1953; 2*s*.). This explains clearly, in the simplest language, what chemical engineering is, how it developed, what a chemical engineer does, his opportunities, and how he can be trained; and it supplements its descriptions with admirable illustrations of plant of diverse nature, designed and constructed by chemical engineers. It is to be hoped that means will be found of bringing this pamphlet to the notice of every schoolboy leaving school, every schoolmaster, and every man at present engaged on National Service.

Modesty, unfortunately, seems to have compelled the authors to refrain from mentioning, except in the vaguest terms, the remuneration a chemical engineer may expect: in this materialistic age, one of the first questions asked by a young man selecting a career is: "What salary shall I get and what are the prospects?" This aspect might well be amplified in a future edition. A further line of thought is aroused by the almost parenthetical mention of teaching as an outlet for chemical engineers. Every academic member of the profession knows only too well the extreme scarcity of good teachers, and this fact must be regarded at the moment as the bottleneck in any scheme for the large expansion of chemical engineering training in Britain. Until steps are taken to induce a far larger proportion of chemical engineers than at present to go in for teaching, any increase in the numbers seeking training, or in funds for laboratory extensions, will be rendered of little avail.

H. E. Watson

WOOL INDUSTRIES RESEARCH ASSOCIATION

REPORT FOR 1952–53

The report for 1952–53 of the director of research of the Wool Industries Research Association* records that the opening of new research laboratories at the Leeds headquarters of the Association has greatly increased the research potential. Three new blocks of laboratory buildings, erected since the end of the Second World War, were officially opened by Lord Swinton in October last year. With a staff now totalling 203, a very considerable variety of research topics has been and is being examined, ranging from *ad hoc* investigations of a purely consultative type, designed to assist industrialists in solving the day-to-day problems of a highly technical industry, to almost purely mathematical analyses of the system of forces acting upon fibre arrays during roller drafting, and of the corresponding and resulting fibre displacements.

Among the many research activities mentioned in the director's report, several are noteworthy for the ingenuity and modernity of the techniques employed. For example, in order to test the theory of carding which has been developed at the Association, an electrical counterpart or analogue of the three-part scribbler has been built. This shows in electrical terms what happens to a discontinuous feed, such as is obtained from the hopper of a card, as it passes through a scribbler of up to three swifts, and with one or more workers and strippers per swift. The device can also be used for predicting the effect of automatic controllers on the behaviour of the card, particularly in respect of possible hunting of the proposed control. This application of electronic computer techniques must mean the saving of much valuable time, to say nothing of the large amounts of actual raw material which would otherwise have to be processed to obtain the required results.

---

* Wool Industries Research Association. Report of the Director of Research for 1952–53 (Publication No. 196). Pp. 27. (From the Association, Leeds, 1953.)

Fibre movement in roller drafting has been studied with the aid of radioactive tracers, the principle being to mix at random into a sliver a certain proportion of labelled fibres, and then to follow the movement of these fibres in the body of the sliver as it passes through successive drafting operations by standard procedures.

In the biological field, work on the identification of fibres by use of the sequence in cuticular scale pattern along the lengths of the fibres has led to a new classification of scale patterns for general use and has given more sensitive criteria for the identification of fibres. Such work may well have valuable applications outside the textile field—for example, in forensic science.

While the above examples may perhaps be cited as outstanding features of the Association's research programme, they are accompanied by a very great deal of less spectacular, but nevertheless invaluable, work of a routine nature.

The problem remains, and is recognized as fundamental by all workers in technological research, of getting the results obtained in the laboratory translated as rapidly as possible into practice in industry. The textile industry is probably no more backward in this respect than others; but it certainly remains true that much information which could, if thoroughly applied, make a very great difference to the technical efficiency of the industry, remains literally a closed book so far as the latter is concerned. This is not necessarily due to any strong prejudice against scientific research, but rather to the difficulty of securing adequate liaison between laboratory and the mill. The Wool Industries Research Association has made a notable attempt to surmount this difficulty by the appointment of liaison officers for this sole purpose. To quote the report on this matter: "The officers' visits give contributory members the advantage of verbal amplification of the Association's publications, and the advantage of discussing the firm's particular problems on the spot. At the same time these discussions enable the officers to keep the Association's staff informed of contemporary conditions and developments in the industry; thus research work can be directed along the most beneficial lines. Points of interest to members are discussed which often result in an investigation being pursued, to the members' very considerable advantage. The officers are also able to arrange for the co-operation of member firms in experimental projects which require large-scale trials or surveys. This two-way passage of information and of the use of equipment was scarcely anticipated when the liaison officers were appointed, but there is no doubt that it is now a valuable feature of their activities".

Such schemes of interchange are, of course, by no means novel in the industry, and are shared by other research associations and by university departments; but it is heartening for those whose foremost aim is the technical betterment of industry through sound research to see the process enlarged.

THE FRAMEWORK OF ASTRONOMY

FOR his inaugural lecture as Perren professor of astronomy in the University of London, which he gave last year at University College, London, Prof. C. W. Allen chose as his subject "The Framework of Astronomy". At the beginning of this lecture, which has now been published*, Prof. Allen points out that the work of the astronomer usually falls into one or the other of two categories: the expanding category, in which are the activities of elaborating, detailing, compiling and investigating individual objects for their own sake; and the contracting category, which includes the work of unifying, consolidating and standardizing. Very appropriate analogues are found in the political realm—namely, individualism and freedom in the first category, and regimentation and good order in the second. Both approaches are necessary in astronomy. The expanding individualism leads to new ideas and discoveries and also to long observational programmes with their risk not only of drudgery but also of the absence of discovery; equally important, however, is the regimentation mentioned under the contracting category, in which the co-ordination of the original facts and even, if required, the addition of missing links, tend to strengthen the subject. Such co-ordinated results frequently reveal not only regularities but also departures from anticipated laws, and the work of consolidation is responsible for results which can be used as a basis for further advances. The interconnexion of consolidated results from different branches of astronomy should lead to a strong stable framework of astronomical knowledge on which the future can build, and a great part of Prof. Allen's lecture is devoted to a consideration of the relation between the framework and the subject as a whole and also of the problems of constructing and using this framework. For the purpose of the lecture the following definition of 'framework' is given: "It is a complete assemblage of interconnected basis facts and quantities of astronomy prepared in readiness for use". It is admitted that no such framework exists; but as the possibility of its existence is not excluded, Prof. Allen discusses it under the above form.

An efficient framework for astronomy would contain information that represents it as a whole rather than the results of particular individuals and would be "concise, factual, and quantitative". An example is taken from the case of a comet. As every computer of cometary orbits knows, from at least three observations over about a week an orbit is computed on the assumption of parabolic motion and from this an approximate ephemeris enables observers to find it for a few weeks. Subsequent observations provide the data for a more accurate orbit, including the eccentricity, to be computed; then finality can be obtained when all the observations (probably extending over several months) are published and, taking planetary perturbations into consideration, a definitive orbit is computed. No improvement is possible with existing observations; but on the comet's next return the procedure could be repeated, and the sets of elements obtained, which represent the definitive orbits, then approach the ideal for the quantitative framework, that is, "it is efficient, representative, accurate and stable". This is typical of most branches of astronomy where there is a hope that improved values will become available and later work will reap the benefit, but there is also the fear that an improvement will change the adopted values and upset work in progress. The analogue of the definitive orbit cannot, however, be used in other branches of astronomy, because values never reach real stability, and in consequence astronomers may set up either a 'rigid' or a 'flexible' system.

---

* The Framework of Astronomy: an Inaugural Lecture delivered at University College, London, 1 May 1952. By C. W. Allen, Perren Professor of Astronomy in the University of London. Pp. 17. (Published for the College by H. K. Lewis and Co., Ltd., 1952.) 3s.

In the rigid framework values of all the important constants, as close as possible to the best determinations at the time of adoption, are selected; but if these values are later found to be in error they are not changed, a correction being applied for those cases that require it, and such a correction can absorb all the effects of improvements in the experimental values. While a rigid framework of this type is necessary for accurate positional astronomy, the one in use at present does not attain perfection; but the data of its framework are used for the preparation of predictions, and, on comparing these with observational results, discrepancies frequently reflect an inaccuracy in the framework data. Whether such inaccuracies occur or not, the original data remain unaltered so that the process of predicting and observing can continue without interruption, and a clear interpretation can be placed on the observations. This rigid system is not, however, suitable in all cases, and in the more rapidly growing subject of astrophysics, where accuracy is relatively low, a flexible system that caters for perpetual improvement is more appropriate. Here, where the quantitative values vary, the progressive astronomer adjusts his outlook to the knowledge that the values are not precisely known, and he is pleased when the constants fluctuate within the domain of their probable errors. This flexible system shows hope of being available for the whole of astronomy, including astrophysics.

The theme is developed by Prof. Allen; but it is impossible in the limited space to deal with the numerous applications referred to, and this article can do little more than direct attention to the importance of the lecture. Towards the end three conditions, as follows, are mentioned as necessary for building an item into the framework of astronomy: a clear concept and suitable definition of the item; evidence that the item is vital to the progress of astronomy; and some estimate of its numerical value. The mean density of the universe is taken as an example on the above basis, although its value is not accurately known. While the density of the visible part made up of stars in external nebulæ is in the neighbourhood of 10^{-30} gm./cm.^{3}, this neglects the possibility of tenuous matter in the inter-nebulæ spaces. For various reasons, including the meagre observational evidence relating to this space, it is pointed out that, if we accept the extreme view of the reddening of the nebulæ as due entirely to gas, the estimate of the mean density of the universe would be increased by a factor of about ten thousand. When the mean density of the universe is open to such doubt, it is realized how far astronomy has still to go. In spite of this doubt, however, the density of the universe has its place in the development of cosmology, and, if it can be placed between the limits $10^{-[illegible]}$–10^{-30} gm./cm.^{3}, it may possibly be restricted to a narrower range in a few years. "It is already built into the astronomy framework as a quantity to be watched and improved by all means available. If we had no other use for astronomy framework, it would at least be interesting and instructive to see it change as the years go by."

COMPOUNDS OF TERTIARY AMINES WITH NITROSYL CHLORIDE AND WITH DINITROGEN TETROXIDE

By Dr. ALAN E. COMYNS
University College, Gower Street, London, W.C.1

ALIPHATIC and aromatic tertiary amines have been found to react in inert solvents at − 78° with nitrosyl chloride and with dinitrogen tetroxide to yield coloured complexes. The aliphatic complexes are brown and the aromatic plum-coloured. They are insoluble in hydrocarbons but soluble in chlorinated hydrocarbons. The formation of such a complex by trimethylamine and nitrosyl chloride was observed by Jones and Whalen[1], but the generality of this reaction, and its significance in connexion with the reactions of amines with nitrosating agents, have not hitherto been recognized. Amines exhibiting this phenomenon include: trimethylamine, triethylamine, dimethylaniline, diethylaniline, *p*-nitroso-dimethylaniline and N-methyldiphenylamine. The three nitro-dimethylanilines did not form such complexes.

As the complexes are stable only at low temperatures, conventional methods of analysis are inapplicable; the molecular ratios in which the reactants had combined in two of the complexes were determined as follows. Known quantities of the two reactants were mixed at low temperature in pentane solution, and that in excess was quantitatively removed by pumping under high vacuum into a trap cooled in liquid air, the reaction vessel being maintained at − 78° or − 100°. The excess, collected in the liquid air trap, was then determined. The complexes studied by this means were those of dimethylaniline with nitrosyl chloride in excess, and of dinitrogen tetroxide with trimethylamine in excess. The results are shown in the accompanying tables.

These results establish the formation of $(C_6H_5)(CH_3)_2N.NOCl$ at − 78°, and of $(CH_3)_3N.N_2O_4$ at − 100°.

A good solvent for such complexes is a mixture of *sym.*-tetrachlorethane with ether (70 : 30 by volume). Qualitative observations of the absorption spectra of some of the complexes were made at − 78° in this solvent. Solutions containing an excess of dimethylaniline with nitrosyl chloride and with dinitrogen tetroxide had almost identical absorption maxima. That with nitrosyl chloride appeared at 398 mμ; and that with dinitrogen tetroxide at 404 mμ.

The electrical conductance of dimethylaniline with nitrosyl chloride was examined in the same solvent

Table 1. DIMETHYLANILINE WITH NITROSYL CHLORIDE
Temp. = −78°
(DMA = dimethylaniline)

Initial ratio NOCl/DMA:	1·53	1·75	1·88	1·92	1·80
Final ratio NOCl/DMA:	1·09	1·06	1·06	1·00	0·91

Table 2. TRIMETHYLAMINE WITH DINITROGEN TETROXIDE
Temp. = −100°

Initial ratio Me_3N/N_2O_4:	1 5	1·5	1·5	1·9	2·1	2·9
Final ratio Me_3N/N_2O_4:	0·89	0·96	0·94	1·14	0·92	1·05

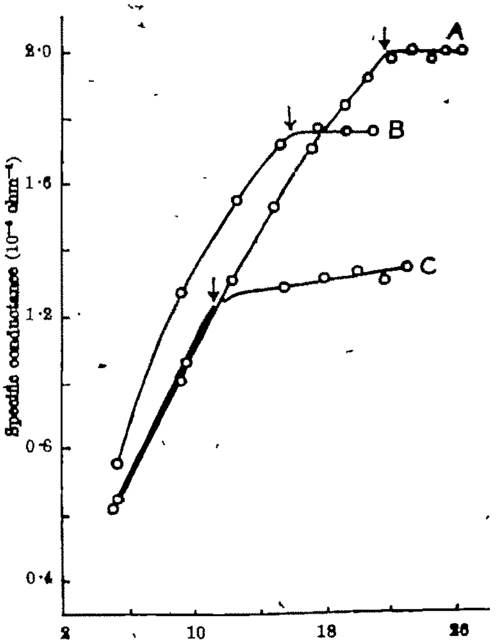

Fig. 1. Normality of dimethylaniline: *A*, 0·0216 *N*; *B*, 0·0158 *N*; *C*, 0·0110 *N*. Equivalence-points marked by arrows

at − 78°. The conductances of a solution of dimethylaniline of constant concentration to which different amounts of nitrosyl chloride had been added are shown in Fig. 1. The conductance rises rapidly with increase of nitrosyl chloride concentration until equimolecular quantities are present, and then remains nearly constant. For comparison, conductance curves for nitrosyl chloride alone, for a tetra-alkylammonium salt, and for dimethylaniline with hydrogen chloride at different concentrations were also obtained under the same conditions, and are shown in Fig. 2. The conductance of the dimethylaniline–nitrosyl chloride complex is of the same order as that of the quaternary ammonium salt, and is much greater than that of dimethylaniline hydrochloride at similar concentrations.

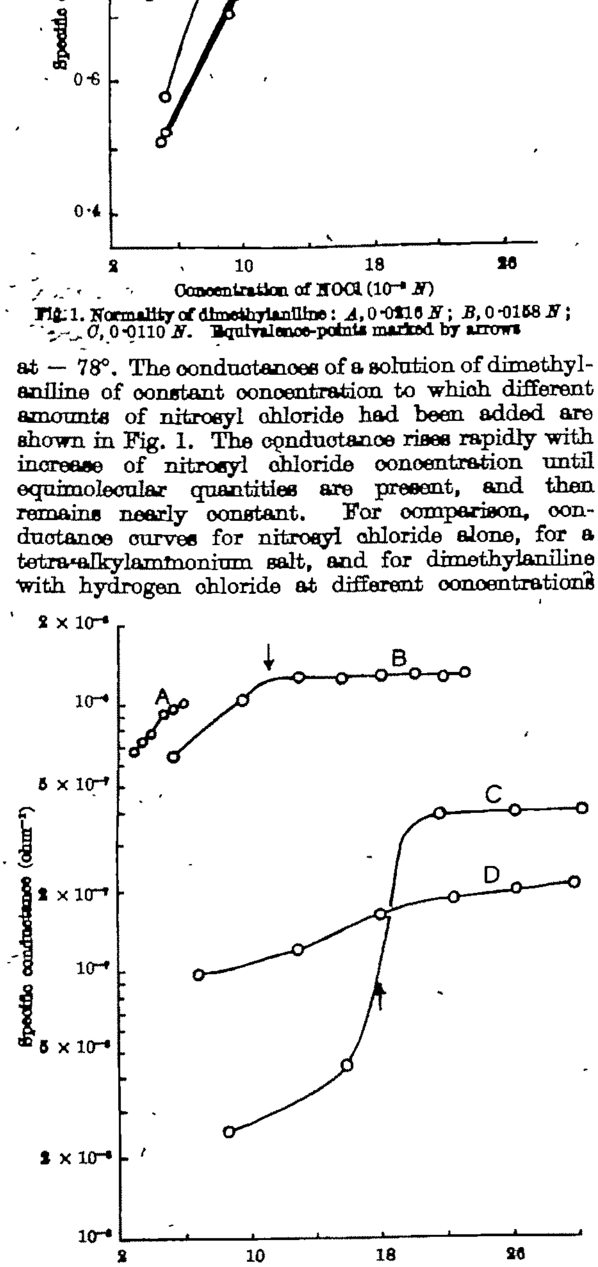

Fig. 2. *A*, Phenyl-trimethylammonium iodide; *B*, dimethylaniline (0·0110 *N*) with nitrosyl chloride (for comparison); *C*, dimethylaniline (0·0179 *N*) with hydrogen chloride; *D*, nitrosyl chloride. Equivalence-points marked by arrows

These results strongly suggest that the complex should be formulated as a nitrosoammonium salt:

$$[(C_6H_5)(CH_3)_2\overset{+}{N}.NO]Cl^-;$$

and the similarity of the absorption spectra indicates that the N_2O_4 complex has a similar structure:

$$[(C_6H_5)(CH_3)_2\overset{+}{N}.NO]NO_3^-.$$

The decomposition of the aliphatic complexes is rapid at −55°; the complexes of the aromatic amines are more stable, and their formation can be observed as a transient brown coloration when solutions of the reactants are mixed at room temperature, before the green colour of the nuclear nitroso-compounds appears. The decomposition products of the complex of trimethylamine with nitrosyl chloride were studied in detail by Jones and Whalen[1]; they included trimethylammonium chloride, dimethylammonium chloride, and nitric oxide. Trimethylammonium nitrate and nitric oxide are likewise products of the decomposition of the complex with dinitrogen tetroxide. The decomposition of the dimethylaniline–nitrosyl chloride complex yields *p*-nitrosodimethylaniline hydrochloride: and this is the product isolated when the reactants are brought together at higher temperatures[2].

The decomposition products obtained by Jones and Whalen from their aliphatic complex agree with those assumed by Hughes, Ingold *et al.*[3] in their suggested mechanism for the oxidative dealkylation of tertiary aromatic amines during nitrosation and nitration. The properties of the complexes obtained in the present work correspond closely with those predicted for the intermediate nitrosoammonium ion postulated for this dealkylation.

I wish to thank Prof. E. D. Hughes for suggesting this investigation, and Dr. R. Passerini for recording the absorption spectra. [April 14.

THE Z-ENZYME IN AMYLOLYSIS

It has been found by Peat, Pirt and Whelan[1] that crystalline β-amylase is unable to promote hydrolysis of amylose beyond about 70 per cent maltose. Progress is arrested by anomalous linkages, which however can be split by the '*Z*-enzyme', postulated for this purpose, that is present in, for example, soya amylase. Evidence was furnished by Peat, Thomas and Whelan[2] which suggested that the *Z*-enzyme is a β-glucosidase. The exact function of the *Z*-enzyme is clearly a matter of considerable interest and importance.

In experiments performed by us we have confirmed the undoubted existence of the arrest point, and, in general, our soya and crystalline amylases behave like those described by Peat *et al.* However, attempts to identify the *Z*-enzyme with β-glucosidase have been unsuccessful. If potato amylose limit β-dextrin is hydrolysed by soya amylase under conditions favourable to the action of the *Z*-enzyme, we should expect glucose to be liberated first, followed by maltose.

Traces of glucose as low as 2 μgm. can be detected by us using paper chromatography, employing the procedure of Partridge[3]. Since many times as much maltose is needed for a corresponding indication, it should be possible under suitable conditions to detect glucose among the reaction products as soon as maltose. In any case, the yield of glucose at an advanced stage of the reaction should correspond to about 1 per cent of the substrate used—if we assume the mean chain-length of the limit dextrin to be a hundred, a reasonable assumption in view of its blue value, method of preparation, etc.

We prepared amylose limit β-dextrin from potato amylose by the repeated action of crystalline β-amylase at *p*H 3·6, dialysis and recovery with butanol. Acting on a 0·1 per cent solution of this with soya amylase at *p*H 5 and 33° C., conditions very favourable to the action of the β-glucosidase of soya, we secured a rapid hydrolysis ultimately reaching beyond 90 per cent maltose. From concentrates of the reaction mixture at intervals, paper chromatograms were run on quantities equivalent to 2 mgm. of the dextrin substrate. Although maltose was absent at the outset but increased during the reaction, no glucose could be detected at 50 per cent hydrolysis. But a withdrawal after the reaction had passed 90 per cent and had apparently ceased revealed about 4 μgm. of glucose in 2 mgm. of reaction products, or 1 in 500. A control hydrolysis with maltose instead of the dextrin gave a fainter spot for glucose. Having regard to the probable action of traces of α-amylase in splitting off chains with an odd number of glucose residues from which glucose would be ultimately formed by the action of the β-amylase, it can be concluded from this experiment that the glucose formed was due to the latter cause, plus the action of the slight trace of maltase present. Furthermore, the changes in absorption values of the iodine colorations were indicative of the intervention of α-amylase in this reaction. It should be added that control chromatograms were run with glucose, maltose and maltotriose in all cases.

As it was possible that for some reason our soya amylase (prepared from soya beans by the method of Newton *et al.*[4]) was deficient in β-glucosidase (a test with cellobiose as substrate was positive), resort was had to emulsin. Two preparations, one specially made from sweet almonds by the method of Tauber, were used, each of which promoted a vigorous hydrolysis of cellobiose at *p*H 5, but each possessing faint α-amylase activity, as is well known[5,6]. In one experiment extract of emulsin was made to act at *p*H 5 and 33° C. on (*a*) 0·2 per cent amylose limit β-dextrin, (*b*) 0·002 per cent cellobiose, (*c*) 0·002 per cent maltose.

The concentration of β-glucosidic groups in (*a*) would presumably equal or exceed that in (*b*). Chromatograms showed hydrolysis in (*b*) to be well advanced in one day and virtually complete in two days. But in (*a*) a trace of maltose though no glucose was indicated in one day, and, after five days, glucose equivalent to 0·3–0·4 per cent of the amylose limit β-dextrin that had been taken. The same amount of glucose had been formed in (*c*) as in (*a*). Enough maltose was present in (*a*) after one day to have provided the maltase present thereafter with more substrate than in (*c*). The active cellobiose-splitting enzyme in the emulsin had failed to split glucose directly from the amylose dextrin, since the small amount formed would be fully accounted for by the actions of amylases and maltase.

Reaction mixture (*a*), brought to *p*H 3·6 and treated with β-crystalline amylase, was hydrolysed almost to completion. A preparation of the *Z*-enzyme from soya amylase behaved, in general, similarly to emulsin and was shown by its faint action on amylopectin limit β-dextrin to contain a faint trace of α-amylase.

These results raise doubts as to the identity of the *Z*-enzyme and β-glucosidase. In considering alternatives, one is continually brought back to α-amylase, traces of which could resemble the *Z*-enzyme. Peat *et al.*[2] ruled out this possibility after experiments in which the *Z*-enzyme was replaced with salivary α-amylase in great dilution. The latter increased the limit of action of crystalline β-amylase on amylopectin, whereas the former failed to do so. One aspect of the action of α- in the presence of a great excess of β-amylase was not discussed in their paper. The internal chains of amylopectin may be taken as averaging 5–6 units in length[7,8]. A single fission of an internal chain by α-amylase would expose, on an average, only three or four glucose residues at most to the action of β-amylase leading to only one more fission, whereas the corresponding result with amylose limit β-dextrin might well be fifty or more residues broken down to maltose. In the presence of great excess of β-amylase, a suitably small amount of α-amylase, while easily measured with amylose limit β-dextrin, could be missed when employing amylopectin, its limit β-dextrin or amylose glycollate as substrate. As regards the last-named, which was used by Peat *et al.*[2] in the determination of α-amylase, it should also be remembered that rate of fall of absorption value at 680 mμ promoted by α-amylase acting alone is relatively low when substrates of great chain-length are employed[9].

Another point is that salivary α-amylase is not typical of all α-amylases in one respect. It can attack α-1,4 glucosidic linkages close to the branch-points in amylopectin; only those connecting to the glucose residues actually involved in the 1,6 linkage are immune to its attack[10]. Malt α-amylase is an example of another type which can easily attack linkages only when they are five or six units away from a non-reducing end or branch-point[11–13]. This means that an internal chain of average length would be less readily split and, when split, this would be at such a position that the length of the chain thereby exposed to the action of β-amylase would be four units shorter than in the corresponding case with salivary amylase. Thus, malt α-amylase would split these internal chains less readily than salivary amylase, and there would be, per fission, less material available for β-amylolytic action. The α-amylase of the soya bean may resemble that of malt. Both occur in Nature in association with β-amylase, which takes over functions of saccharification.

Amylolyses of amylose and amylopectin by β-amylase containing a slight trace of α-amylase in parallel experiments present the following contrasting features. Because of the relatively large number of chain-ends on which the enzyme can act, β-amylase hydrolyses amylopectin in dilute solution many times faster than amylose. After completion of the purely β-action, subsequent action on amylopectin is restricted by the rate at which traces of α-amylase present can promote fissions of the internal chains. The shortness of the latter restricts both the affinity of some α-amylases and any further fission by the β-enzyme. This second phase, for one if not both of the reasons given above, must be exceedingly

ACTION OF β-AMYLASE ON α-TREATED AMYLOSE AND Z-TREATED AMYLOSE

	Time of β-amylolysis (hr.)	0	0·25	0·5	1·0	1·5	2·5	5·75	9·25	20·25
Z-treated amylose	B.V. (680 mμ)	1·42	1·08	0·850	0·622	0·530	0·374	0·171	0·094	0·040
α-treated amylose		1·33	0·86	0·628	0·393	0·301	0·231	0·174	0·168	0·161

slow compared with the corresponding fission of amylose in the second phase. Thus, with a suitable addition of such amylase, amylolysis of amylopectin would stop (within the limits of experimental error), whereas that of amylose would continue.

The possibility that Z-enzyme action is due to a suitably low trace of α-amylase in our opinion merits further investigation. All the phenomena reported by Peat *et al.*[1,2] can be explained on such a basis—for example, the limits of action of phosphorylase in the presence and absence of the Z-enzyme. Even the failure of mercuric ions to inhibit the action of the Z-enzyme or emulsin is not conclusive proof that their actions are not due to α-amylases. The latter, unlike β-amylases, are not necessarily inactivated by mercury compounds[14], are not inactivated on the acid side of the *p*H optimum[15] and, when inactivated, the process takes time[16].

Our specimen of crystalline β-amylase is contaminated with a minute trace of α-amylase, as shown by its action at *p*H 6 on amylopectin limit β-dextrin.

One point we would like to add: an amylose described by Hopkins and Jha[17], which was prepared from potato starch by infusion at 63° C. followed by precipitation by thymol, was hydrolysed rapidly to 78 per cent by crystalline β-amylase at *p*H 3·6 reaching a limit at 80 per cent, whereas the amylose left behind in the starch granules, in its turn separated by thymol, was correspondingly hydrolysed only to 59 per cent with a limit at 64 per cent.

We are indebted to Dr. A. K. Balls for his gift of crystalline β-amylase.

WE are glad of the opportunity of commenting on the communication of Prof. Hopkins and Dr. Bird, which raises the old doubt that Z-enzyme is in fact a weak α-amylase. In our paper[1] we emphasized the necessity of distinguishing Z-enzyme from α-amylase, and we concluded that the experiments there detailed did in fact do so. Prof. Hopkins now discounts the evidence of experiments in which amylopectin or amylose glycollate were the substrates on the grounds that these methods of detecting weak α-amylase activity were insufficiently sensitive, a conclusion for which no experimental evidence is afforded. We do not share this view; but we would point out that all our evidence is not based on experiments with amylopectin or amylose glycollate. One of these, which we regard as conclusively showing that Z-enzyme is not an α-amylase, has apparently been overlooked by Hopkins and Bird, although it conforms with their view that amylose is a better test substrate for α-amylase than is amylopectin. The results of this experiment are re-stated below, together with further details not reported at the time.

A highly purified amylose was used as the substrate in two parallel experiments in which were examined the successive actions of (1) Z-enzyme followed by β-amylase, and (2) a weak salivary α-amylase followed by β-amylase. The amylose (B.V. 1·47; for definition of B.V. see ref. 2) was digested with Z-enzyme for ten hours, during which time the B.V. fell to 1·42. When the amylose was similarly treated with the highly diluted α-amylase, the degradation was more extensive, the B.V. falling to 1·33. In each case the enzymes were then inactivated by heat and crystalline β-amylase was added. The changes in iodine-staining power observed are shown in the table.

These figures show that Z-enzyme action, which resulted in a smaller initial change in B.V. than did α-amylase action, enabled a more complete β-amylolysis to take place, although the rate of β-amylolysis of the α-treated amylose was at first greater than that of the Z-treated amylose. The limiting percentage conversions into maltose (measured by the copper-reducing power) supported the evidence of iodine-staining, being 89·4 per cent for α-treated amylose and 97·7 per cent for Z-treated amylose. Thus it is clear that Z-enzyme exerts a true debranching action, enabling complete β-amylolysis to take place. It does not fragment the amylose molecule after the fashion of α-amylase, the action of which enzyme is such as to leave iodine-staining fragments of the molecule still protected from β-amylase action by the anomalous (Z-labile) links.

A second point which calls for comment concerns the liberation of glucose by soya amylase. At the end of our paper[1] we suggest that the Z-labile links in amylose join single glucose residues to the main chains, and we quote certain facts which support this suggestion. The failure of Hopkins and Bird to detect the liberation of glucose by their sensitive paper-chromatographic method does not mean that β-linkages susceptible to Z-enzyme action do not exist in amylose, but simply implies that our suggestion limiting the branches to single glucose 'stubs' may be incorrect.

Audio-Frequency Spectrum of Atmospherics

The observations on the low-frequency or 'slow tail' component in the waveform of an atmospheric described recently by Hepburn and Pierce in *Nature*[1] is of particular interest to us since we have been making similar observations for some years. The earlier observations made by Appleton and Chapman[2] dealt with the evolution of atmospheric waveforms. It was shown that many atmospherics consist of an oscillatory portion, composed of a sequence of quasi half-cycles of increasing duration, followed by a 'slow tail' of usually two rounded half-cycles. The oscillatory portion was found to move ahead of the slower disturbance as the distance of propagation increased. Further, the quasi half-period of the components of the oscillatory portion was found to obey a relation different from the 'slow tail'.

During the past few years we have supplemented the waveform observations by simultaneously recording the different frequency components in the spectrum of atmospherics from the response of a number of narrow-band tuned receivers[3]. The results given below were derived from an apparatus covering the frequency range 40 c./s.–16 kc./s. split by twenty-seven band-pass filters arranged logarithmically at three channels per octave. The amplitude frequency spectrum is presented directly on the screen of a cathode-ray tube and photographed with the corresponding waveform in order that there should be no doubt as to the type of atmospheric to which the spectrum relates. The records obtained show in a striking way the relative amplitudes of the spectrum components in the oscillatory portion and 'slow tail' of atmospherics as recorded at different distances from the source. Like the Cambridge workers, we are indebted to the Meteorological Office "Sferics" Organization for the location of sources of atmospherics.

In Fig. 1 is shown the relative amplitude of the frequency components $G(\omega)$ for atmospherics of the type described above as received at four different distances from the source. The parts of the spectrum resulting from the 'slow tail' and the higher-frequency precursor are indicated. As is to be expected, $G(\omega)$ decreases as the distance of propagation increases; but an interesting feature of the curves is that the frequency of the greatest component in the 'slow tail' decreases as the distance increases, while for the higher-frequency oscillatory portion the opposite effect occurs. The marked drop in the curves at frequencies in the region of 2 kc./s. and the widening of the trough with distance are indicative of selective attenuation of these components on an increasing scale with distance.

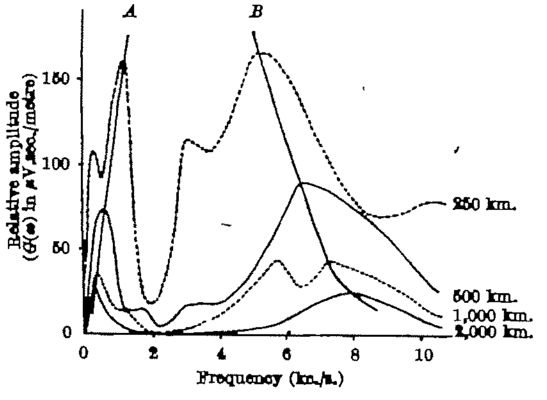

Fig. 1. Relative amplitude of the frequency components of atmospherics resulting from 'return strokes' of lightning flashes observed by day at different distances from the source. (*A*) shows the effect of distance on the maximum component in the 'slow tail', and (*B*) the corresponding effect for the higher-frequency oscillatory portion

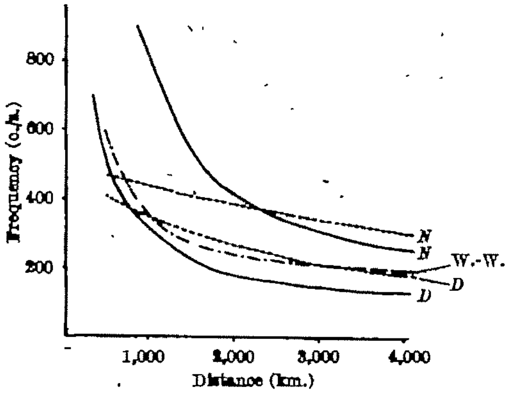

Fig. 2. Effect of distance on the frequency of maximum components in the 'slow tail' of atmospherics. Results as follows: ———, Chapman and Matthews; – – – –, Hepburn and Pierce; —·—·—, Watson-Watt. *D*, day; *N*, night

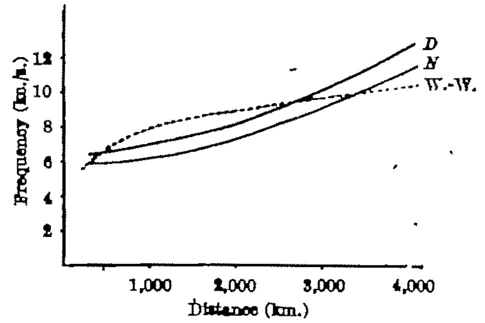

Fig. 3. Frequency of maximum components in the oscillatory portion of atmospherics compared with results deduced from waveform observations by Watson-Watt (indicated as W.-W.) at various distances from the source. *D*, day, *N*, night

An exact comparison of our results with those of Hepburn and Pierce[1] and Watson-Watt, Herd and Lutkin[4] for the 'slow tail' is not possible, since their data were obtained from a measurement of the quarter-period $\tau/4$, the time occupied by the first quarter-cycle of the 'slow tail' waveform. If we assume τ does, in fact, relate to maximum frequency components, and taking $1/\tau$ as the frequency at which these occur, we may compare the variation of this quantity with distance with our data. Fig. 2 shows our spectrum results for atmospherics received under both day and night conditions of propagation, together with the corresponding curves derived as above from the data supplied by Hepburn and Pierce[1]. Watson-Watt, Herd and Lutkin[4] did not specify day or night observations. All the results show the same general trend and indicate clearly that the frequency of the greatest component in the 'slow tail' for a given distance is higher at night than by day, whereas for the oscillatory portion, Fig. 3, not dealt with by Hepburn and Pierce, it is lower at night than by day.

This investigation is part of a long-term study on the spectrum of atmospherics and has been aided by grants from the Department of Scientific and Industrial Research. A detailed account of the present work is in course of preparation.

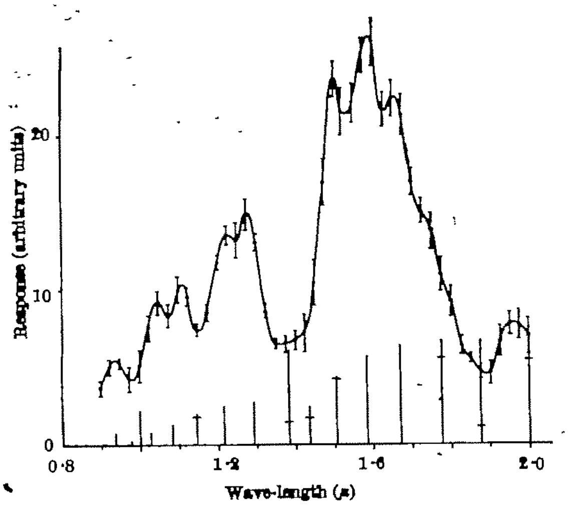
Spectrum of the Night Sky in the Range 1·2–2 μ

We have recently obtained a series of spectra of the night sky in the wave-length region 1–2 μ. A lead sulphide cell was used as the detector in a grating spectrograph normally used for photographic spectroscopy[1]. The spectrum was scanned across the detector by rotating the grating, and spectra were obtained in the first order of the 15,000-lines/in. grating, using a 7–56 Corning filter to eliminate radiation of wave-length less than 0·9 μ.

The graph shows a plot of cell signal against wave-length, the average of five runs obtained at Saskatoon during the nights of June 14, 21 and 22, 1953. The spectrometer was directed towards a point in the sky about 15° above the northern horizon. Artificial lights were absent in this direction for a distance of at least twenty miles, and the atmosphere within the field of view of the spectrograph was not illuminated by the sun below 120 km. The spectral slit width used was 200 A., while the scanning-rate was 1 μ/hr. The standard deviation of the points obtained from individual runs is indicated by the length of the vertical lines through these points.

The most striking feature of the spectrum is the strong emission in the neighbourhood of 1·5 μ. It is possible to interpret this as being due to the $\Delta v = 2$ sequence of the OH rotation-vibration bands, the higher sequences of which were discovered in the night-glow spectrum by Meinel[2]. In the graph, below the spectrum, the positions and intensities of the OH bands as predicted by Heaps and Herzberg[3] have been indicated; the lengths of the vertical lines have been drawn in proportion to the predicted intensities. Since it is probable that the OH emission originates from a height of about 70 km.[4], it is to be expected that the band intensities will be strongly modified by atmospheric water-vapour absorption, and the horizontal strokes across the lines indicate the intensities as corrected for this absorption, the correction being, of course, rather uncertain[5].



Over the range 1·2–2 μ, the observed bands can be satisfactorily attributed to OH bands; at shorter wave-lengths the agreement is poor. We attribute this to the low signal-to-noise ratio in this region, since Kron[6] and Krasovsky[7], using detectors of greater sensitivity, have obtained general agreement with the OH bands up to 1·2 μ. Still, it is possibly worth noting that we have observed very intense radiation between 1·0 and 1·1 μ from the aurora, and it is therefore possible that low-level auroral activity, which is common in these latitudes, has distorted the night-sky spectrum in this spectral range.

Further investigations of the night sky and auroral spectra in this wave-length region are in progress.

The research reported here has been sponsored by the Geophysics Research Directorate of the Air Force Cambridge Research Center, Air Research and Development Command, under Contract *AF* 19(122)–152.

Difference of Temperature between Pole and Equator of the Sun

Both Emden's[1] old hydrodynamic solar theory and the more modern thermo-hydrodynamical solar theory due to Bjerknes[2] lead to a higher temperature at the poles than at the equator of the sun. Bjerknes's theory is, however, more definite as regards the order of temperature difference to be expected. Bjerknes regards the sun as a baroclinic cosmic vortex in which there is a stratified circulation directed from the poles to the equator in the upper photospheric layer and a reverse circulation in the layer immediately below. According to him, sunspots, which he considers also to be vortices, originate in the sub-photospheric stratum; and the depth of a sunspot vortex is connected with the actual difference of temperature between the pole and the equator of the sun. This difference of temperature thus acquires a special importance in solar physics, and therefore an observational determination of this quantity is greatly to be desired. To our knowledge, no measurement of this quantity is so far available. The reason for this lacuna is perhaps to be found in the difficulty of measuring the temperature of the sun with the required degree of accuracy; for the usual methods of measuring the effective temperature of the sun cannot be trusted to give an accuracy greater than ± 400° or 500°. But the temperature difference between the poles and the equator might be of the order of 100° or even less, so that some procedure capable of a higher precision is evidently required.

Some twenty years ago, Woolley[3] evolved such a procedure, which he called the method of "calcium ionization temperature" and which could give an accuracy of ± 50° or better. Recently, during a period of conspicuous solar inactivity and under perfect observing conditions, we were able to apply this method to the determination of the temperature difference between the pole and the equator. Our measurements were aimed at the evaluation of the equivalent widths of the λ 4227 line due to the neutral Ca atom and the λ 3933 line due to the ionized Ca+ atom at the pole and at the equator from nearly two hundred solar spectra secured under high dispersion. All these spectra yielded concordant values for the equivalent breadths. Our final evaluation of the pole–equator difference of temperature, which was done in accordance with Woolley's theory, led to the conclusion that the temperature at the pole is measurably higher than at the equator. In the calculations we used two alternative theoretical values for the ratio of the coefficients of continuous absorption at λ 3933 (k_1) and at λ 4227 (k_0) derived by Pannekoek[4] and by Chandrasekhar[5]. Pannekoek's value of $k_1/k_0 = 1 \cdot 35$ gave a temperature difference of 96° ± 18°, while Chandrasekhar's more recent value $k_1/k_0 = 0 \cdot 925$ gave 86° ± 16°.

One can derive the depth of a sunspot umbral column from Bjerknes's theory by using the observed difference of temperature between the pole and the equator. From the above values the depth of a sunspot vortex works out as 125 km. and 140 km. respectively. It is perhaps significant that these depths are of the same order as those deduced by Milne[6], Petrie[7] and Unsöld[8] from entirely different theoretical considerations. It is therefore not improbable that the umbral temperature of sunspots may yet turn out to be one of the solar constants as imagined by Milne many years ago.

Full details of our observational procedure and of our method of calculation are given in a paper which will form part of "Vistas in Astronomy", a book (now in the press) dedicated to Prof. F. J. M. Stratton, of Cambridge, on his seventieth birthday.

Thermodynamics of Irreversible Electrochemical Phenomena

IN a recent letter in *Nature* Kemp[1] postulates, in opposition to our views[2–5], as the basic equation for the treatment of irreversible electrochemical processes, the formula:

$$T\mathrm{d}s/\mathrm{d}t = \mathrm{d}u/\mathrm{d}t + p\mathrm{d}v/\mathrm{d}t - \sum_k \tilde{\mu}_k \mathrm{d}c_k/\mathrm{d}t, \qquad (1)$$

where s and u are the entropy and the energy per unit mass of the system; v is the specific volume, $\tilde{\mu}_k$ the electrochemical potential per unit mass and c_k the mass fraction of component k (see ref. 6 on this subject). In this connexion, we would like to make the following remarks.

(1) The energy in Kemp's equation is not well defined. In fact, such an equation has never been derived from first principles, that is, from the first and second laws of thermodynamics. In order to obtain such an equation it is in the first place necessary to write down the first law for open systems[7]. A consistent treatment[2,3] starting from the law of conservation for the density of total energy (which includes the density of internal energy, the density of macroscopic kinetic energy, and the density of electromagnetic energy) leads, instead of (1), to:

$$T\mathrm{d}s/\mathrm{d}t = \mathrm{d}u/\mathrm{d}t + p\mathrm{d}v/\mathrm{d}t - \sum_k \mu_k \mathrm{d}c_k/\mathrm{d}t, \qquad (2)$$

where u is the *internal* energy per unit mass of the system and where μ_k is the chemical potential of component k. On introduction of the electrochemical potential $\tilde{\mu}_k$, (2) can alternatively be written:

$$T\mathrm{d}s/\mathrm{d}t = \mathrm{d}\tilde{u}/\mathrm{d}t + p\mathrm{d}v/\mathrm{d}t - \sum_k \tilde{\mu}_k \mathrm{d}c_k/\mathrm{d}t - e\mathrm{d}\varphi/\mathrm{d}t, \qquad (3)$$

where e is the total electric charge per unit mass of the system and where the energy $\tilde{u} = u + e\varphi$ also includes the 'potential' energy $e\varphi$.

It is apparent from Kemp's letter that his energy u in equation (1) is identical with our $\tilde{u}$ of equation (3); although he obviously confuses this quantity with our u (equation 2), the internal energy. In fact, Kemp writes: "the intrinsic energy U does, by definition, include the totality of the energy contained in the system, so the addition of the term $e\varphi$ is tantamount to including the electrical energy twice over".

(2) It is rather surprising that one should arrive at the same results regarding the thermodynamical "driving force" acting on a charged component from equation (1) as from the different equation (2) or its alternative form (3).

(3) According to Kemp: "Since the change in U is quite independent of the path followed, it is quite correct to apply this equation [equation (1) or (2)] to any process whatever occurring in the system, reversible or irreversible". However, the application of Gibbs's equation to irreversible processes, that is, outside equilibrium, is, from a macroscopic point of view, an assumption only to be justified by statistical methods. In fact, it has been shown that the use of Gibbs's equation is only a good approximation for 'small' deviations from equilibrium[8].

(4) Finally, we would like to illustrate once more the importance of the term $e\mathrm{d}\varphi/\mathrm{d}t$ in equation (3), as well as the paradoxical results arrived at with equation (1). Consider a purely formal change $\mathrm{d}\varphi$ of the gauge of φ which is possible according to general electrodynamics, while $\mathrm{d}v = 0$, $\mathrm{d}c_k = 0$. Then $\tilde{u}$ changes as a consequence of the gauge transformation by an amount $\mathrm{d}\tilde{u} = e\mathrm{d}\varphi$, so that, according to equation (3):

$$ds = 0, \tag{4}$$

as it should be for this formal change.

Equation (1) would lead to the obviously wrong result $ds \neq 0$, whereas equation (2), which is entirely unaffected by the change of the gauge of φ, again yields the correct result, equation (4).

[8] Prigogine, I., *Physica*, 15, 272 (1949).

The above letter by Prof. S. R. de Groot and his co-workers has directed my attention to an error in my earlier communication[1], but has also made more obvious the fundamental error in their own paper[2].

In that paper they considered a medium showing a bulk motion and in which chemical reactions and flows of energy, matter and electricity were occurring. Their treatment was in effect a detailed consideration of the thermodynamics of a system consisting of an elementary volume of that medium. In virtue of the flows of matter, this system is an open one, and the work which it can perform is thus of four kinds: volume work, osmotic work, electrical work arising from changes in the concentrations of the charged components, and electrical work arising from changes in the electrical potential of the system. Using Gibbs's equation, we thus have, expressing the extensive properties in terms of unit mass:

$$Tds = du + pdv - \sum_k \mu_k dc_k - \sum_k e_k \varphi dc_k - e d\varphi, \tag{1}$$

or, introducing the electrochemical potentials:

$$Tds = du + pdv - \sum_k \tilde{\mu}_k dc_k - e d\varphi. \tag{2}$$

Equation (2) differs from that of my earlier communication, in which the last term on the right was erroneously omitted, and now leads to profoundly different conclusions.

The question of the validity of Gibbs's equation in relation to the present problem is of extreme importance, but is not the point now at issue. It may be noted, however, that de Groot and Tolhoek in their original paper[2] made use of Gibbs's equation without any hesitation.

If the formal change $d\varphi$ in the gauge of φ is now made at constant volume and composition, the specific internal energy u changes by an amount $e d\varphi$, corresponding to the formal change in the potential energy which has now occurred; all other terms on the right of equation (1) or of equation (2) are zero except the last, $- e d\varphi$. Hence we have the necessary result $ds = 0$.

Instead of equations (1) or (2), de Groot and his co-workers use for Gibbs's equation:

$$Tds = du + pdv - \sum_k \mu_k dc, \tag{3}$$

and the same argument shows that, contrary to their claim, the formal change in the gauge of φ now incorrectly yields $ds \neq 0$. Thus it is equation (3) and its various other forms (all identical in physical content) which are at fault, not equation (1). In fact, equation (3), which contains no electrical terms whatever, cannot possibly apply to the system under consideration.

When equation (1) is employed in place of equation (3) in the study of the system under consideration, it is found that the entropy production can be written as the sum of a product of thermodynamic forces and fluxes. Furthermore, with a suitable choice of forces and fluxes, the quantities μ_k and e_k appear in the expression for the entropy production only in the combinations $\tilde{\mu}^k$, provided that the condition $e = 0$ applies. This result implies that φ can be measured separately from the μ_k only if $e \neq 0$, that is, if a space charge is present in the system.

These conclusions are now identical with those of de Groot and Tolhoek, although these authors employed an incorrect form of Gibbs's equation. In arriving at these conclusions, however, they employed only the force equation (equation of motion for the kth component), which is not affected by any errors made in Gibbs's equation. The correct form, equation (1), of the latter now allows the same conclusions to be obtained directly from the entropy balance equation.

Structure of Meta-aminophenol

A single crystal of meta-aminophenol was previously studied[1] by means of rotation photographs only, whereby the identification of spots remains doubtful. We used the Weissenberg method and identified the spots by the method of Schneider[2]. We also studied the optical properties of this crystal.

The crystals were obtained by slow evaporation of alcohol solution. The crystal is orthorhombic with the following axial data: $a = 6 \cdot 31$ A., $b = 11 \cdot 12$ A., $c = 8 \cdot 60$ A.; with density (observed) 1·195, η the number of molecules per unit cell is 4. With these data, density was calculated to be 1·206.

The crystal was found to be optically negative with the values of refractive indices γ, β and α along a-, b- and c-axes, respectively: $\gamma = 1 \cdot 638$, $\beta = 1 \cdot 625$ and $\alpha = 1 \cdot 505$, and $v_a = 15° \; 30'$, where v_a is half the optic-axial angle.

If the molecules form a parallelism among themselves then the plane of the benzene ring will have a least value of refractive index perpendicular to the plane of the ring.

This result shows that the plane of the benzene ring is closer to the α- and β-directions than to the γ-direction.

Over-exposed oscillation photographs about the three crystallographic axes were taken in a Weissenberg goniometer using Ni-radiation. The spots were identified by drawing the requisite Weissenberg charts by the method of Schneider[2]. There are no absent spectra of (hkl). When l is odd $(h0l)$ is absent, but not $(0kl)$. The probable space group is P_{na} (C^{9}_{2v}).

Structure of Selenium Tetrafluoride

In his interesting communication on the structure of SeF_4 [1], Mr. Bowen writes: "Only one model was found to give satisfactory agreement with the visually estimated ring intensities. This model has a distorted tetrahedron of fluorine atoms around the selenium atom with two opposite FSeF angles of 120° and the remaining four FSeF angles equal to 104·5° . . . the uncertainty in the angles [is] ± 10° ".

Now the relationship between the six internal angles in a distorted tetrahedron the corners of which remain equidistant from the centre is

$$\cos^2\frac{\alpha}{2} = -\cos\beta, \text{ or, } \cos\alpha + 2\cos\beta = -1,$$

where α is one of the *two* equal angles, while β is one of the *four* equal angles. For $\alpha = 120°$ we have $\beta = 104° 29'$, in agreement with Mr. Bowen's results. The α values of 110° and 130° yield, however, 109° 13′ and 100° 17′ for β, respectively. Hence 120° ± 10° for α corresponds with 104° 29′ ± *c.* 4° 30′ for β.

It may be of interest to note that, while the analogous six angles in a regular tetrahedron are equal to $109° 28' = \sec^{-1}(-3)$, those quoted by Mr. Bowen are $\sec^{-1}(-2) = 120°$ and $\sec^{-1}(-4) = 104° 29'$. I should like to add that angles formed by the maximum number of equally spaced radii with a common origin are equal to $\sec^{-1}(-1)$, $\sec^{-1}(-2)$ and $\sec^{-1}(-3)$, for the uni-, bi- and ter-dimensional space, respectively.

Separation of Racemic Mixtures by Electrophoresis in a Strong Centrifugal or Magnetic Field

The separation of racemic mixtures of optical isomers is still limited, with rare exceptions, to the methods of Pasteur. For this reason the resolution of substances which seem identical in the test-tube but are importantly different in biology usually proves to be difficult and expensive both in research and in the chemical industry.

A theory for a generic method must be stated in terms of a gross model. The derivation of equations for the movement of a body in an electromagnetic field becomes almost prohibitively difficult except in the case of a sphere or an ellipsoid, as Alexander Kolin[1] has found in his study of the migration of visible particles. Furthermore, the molecules of water are far from infinitesimal in size when compared with the important racemic substances. Since the solvent is not a 'uniform homogeneous fluid', any application of the theorems of hydrodynamics will have at best only qualitative validity.

Consider a racemic mixture—*d*- and *l*-phenylalanine, for example—in a solution which will cause ionization as an acid. Suppose a low-voltage electrophoretic current to flow through the solution, and a strong centrifugal or a non-homogeneous magnetic field to be at right-angles to the direction of molecular migration.

A simple model may be pictured as follows. One may imagine a large number of small boats drifting on a lake, the boats being identical excepting that half have their rudders permanently fixed ten degrees to the right, and the other half ten degrees to the left. Let us further imagine a light wind in a given direction. The boats which were floating at random will tend to be turned with their prows in the same direction as the wind, since they can move in this direction with least resistance. One may ordinarily picture the two sets of boats as diverging at a constant angle according to the setting of the rudders. If there should be sufficient increase in momentum, however, the angular departure from the direction of the wind would increase until the boats are broadside to the wind. Here they will again be oriented with the wind after making a loop or node. In either case, the two groups of boats will travel with an increasing separation to the right and to the left from the direction of the wind.

This physical model corresponds to the specifications stated for the amino-acid mixture. The electrophoretic current corresponds to the wind, the ionization as an acid furnishes the prow and stern polarity, and the asymmetry of the molecules corresponds to the fixation of the rudders to the right or to the left. Finally, the action of the magnetic field upon the most strongly diamagnetic part of the molecule, or else of the centrifugal field upon the part of the molecule with greatest density, will provide the equivalent of a keel with a constant downward direction in the lake.

A sharp resolution, of course, would require the use of a solvent that will minimize the disturbance of Brownian movement. This can be achieved by cooling the water to the point of maximum density, or, in appropriate cases, by using a solvent which remains liquid at a much lower temperature.

The Delhi Pillar

The freedom from rusting of the famous iron pillar at Delhi has long been a subject of comment and has been attributed by some writers to the peculiar properties of the ancient iron from which it is forged. Although some particulars of its history are obscure, it seems certain that the pillar dates from about the fifth century A.D. and is roughly 1,500 years old. The immunity of iron from rusting over such a long period is a striking phenomenon and it may therefore be of interest to report the results of some experiments that were made to ascertain the reason for this.

Table 1. ATMOSPHERIC CORROSION OF STEEL AND ZINC

Exposure station		Corrosion rate. Mils (0·001 in.) per year	
		Steel*	Zinc
Delhi	1950–1951	0·28	—
	1951–1952	0·17	0·006
Godalming	1951–1952	1·7	0·042
Sheffield	1951–1952	4·2	0·61
Khartoum	Average, 9 yr.	0·1	0·02
Basrah	„ 8 „	0·6	0·04
Singapore	„ 10 „	0·6	0·04

* The specimens exposed at Delhi, Godalming and Sheffield were of steel containing 0·3 per cent of copper. This material is roughly one-quarter less corrodible than ingot iron, of which the Khartoum, Basrah and Singapore specimens were made.

Small specimens, 4 in. × 2 in., of steel (⅛ in. thick) and zinc (1/20 in. thick) were exposed in the open air near the pillar for one year and their losses in weight were then determined after the corrosion products had been removed. Their corrosion-rates found in this way are compared in Table 1 with the results of similar tests made at other stations, both at home and overseas.

It is clear that the corrosive conditions at Delhi are very mild. Indeed, the zinc specimens were so little corroded that they retained much of their original polish after a year's exposure there. In my view, therefore, the lack of serious rusting of the pillar is to be attributed to the mildness of the local climate rather than to any intrinsic superiority in the corrosion resistance of the iron itself.

This conclusion is supported by a study of the meteorological data for Delhi, for which I am indebted to the Indian Meteorological Office. The figures for 1951, which fell within the experimental period, are given in Table 2.

It is known from the classical researches of W. H. J. Vernon that the relative humidity of the air is the primary controlling factor for the atmospheric corrosion of iron and that little or no rusting occurs unless the humidity exceeds 70 per cent. The records show that this critical value would only be reached at Delhi for a short time during the whole year. Presumably, too, the sulphur pollution of the atmosphere, which, as Vernon demonstrated, controls the corrosion rate when the humidity reaches the critical value for rusting, is but slight in the neighbourhood of the iron pillar.

The late Sir Robert Hadfield, who was very interested in the Delhi pillar and published an analysis of its iron, seems to have been of a similar opinion, for in one of his papers he prefaces his remarks about this and other specimens of historical interest by observing that "in dry air the action of corrosion may be very slight".

High R^z Frequency in the Blood of Australian Aborigines

IN blood genetic surveys conducted prior to 1948 on Australian aborigines it was shown[1] that these natives possessed the gene R^z, and that its distribution in various Australian States appeared to be patchy. In all, the gene was demonstrated seven times (3 per cent) in 234 aborigines. It was found in natives of Queensland and the Northern Territory, but not in fifty-nine natives of South Australia.

One of us (J. B. B.) is at present engaged on an extensive field survey of aborigines in Western Australia and is also collecting blood samples for testing in Melbourne.

To date, the results in relation to the gene R^z are as follow:

Location	Number tested	R^1R^z	R^2R^z	R^zR^z
Cundeelee Mission	22	2	1	0
Wiluna	33	2	1	1
Cosmo Newberry	59	2	–	0
Mulga Queen	16	0	–	0
Mount Margaret	45	1	–	0
Jigalong Mission	47	7	–	1
Marble Bar	108	1	–	0
Pilgangoora	65	3	–	1
	395	18	2	3

Only seventeen samples of type Rh_1Rh_z from Cundeelee Mission and Wiluna in a total of 134 found have been tested with anti-*hr′* (anti-*e*) serum owing to shortage of this testing reagent. Other examples of R^2R^z probably remain undisclosed in the series. The purpose of this letter is to report finding the genotype R^zR^z in Western Australia, three examples of which occurred in 395 unmixed aborigines tested in the present survey, and the high R^z frequency averaging 6 per cent, but approaching 20 per cent in certain tribes. One previous example of R^zR^z has been reported[2] in the blood of an aboriginal in Queensland.

Tests have been made to date covering the *A–B–O*, *M–N–S*, *Rh*, *P*, Le^a, Fy^a, *K*, Lu^a and *He* blood groups. It has, however, been necessary to limit severely the number of tests performed with some anti-sera owing to world shortage. It can be said as a progress report that in Western Australian aborigines the percentage of *P*+ is about 25, *Fy*(*a*+) is almost 100, *Le*(*a*+) is about 3·5, while *S* of *M–N*, *K*, Lu^a and *He* antigens are absent, or rare. One example of the *Rho* variant presumably homozygous (CD^ue/CD^ue) has been detected in the series; the sample showed weak agglutination with some highly potent anti-*Rho* sera, and failed to agglutinate with others. As judged by strengths of agglutination with specially selected testing sera, it is suspected that an occasional variant occurs at the other *Rh* loci also. Tests made to date on 125 random adult blood samples have failed to show any evidence of the sickle-cell trait in this population.

The full blood-grouping results will be reported after the field survey concludes about the end of 1953.

Theory of Revertible Mutations

GENE mutation studies of a single locus—the incompatibility gene complex in *Oenothera organensis*—revealed mutations of two types: (1) permanent inactivation or losses; (2) revertible changes which included delayed mutations.

Both of these occurred spontaneously and were induced by X-rays. Because of the novelty of revertible X-ray mutations the nature of the induced changes has been discussed at some length[1] and it was shown that they were probably due to genuine gene mutations which reverted back to the normal allele after one to seven cell divisions after mutation. It was suggested that the revertible mutations were due to losses of only a fraction of the total number of polypeptide chains of which the gene is presumed to be composed. It followed that the reversion was due to the sorting-out of the unmutated from the mutated chains, the revertible being the unmutated chains and the delayed being the mutated chains, as suggested by Darlington[2] for delayed mutations induced by mustard gas.

Although alternative explanations for the revertible changes in *Oenothera* were difficult to reconcile with the data, the possibility of a dauermodification due to the cytoplasm was not entirely excluded. Similar studies in *Prunus avium* have now proved beyond doubt that these revertible changes are genuine gene mutations. As in *Oenothera*, the incompatibility gene consists of at least two mutationally distinct parts—or on one definition, two genes. One controls the pollen and the other the style reactions: these can readily be distinguished by precise tests.

The incompatibility tests of a seedling of *Prunus avium* which was obtained by self-pollination with a pollen grain carrying an X-ray induced mutation are given in the accompanying table.

RESULTS OF TEST CROSSES WITH A MUTANT SEEDLING OF *Prunus avium* INDUCED BY X-RAYS

The incompatibility of the mutant on the parent shows that the incompatibility alleles $S_{3'}$ and $S_{4'}$ are active in the pollen. The self-compatibility and the compatibility as female with the parent shows that one of the alleles is inactive in the style

	Result	
Mutant $S_{3',4'}$ selfed	+	
Parent $S_{3,4}$ × Mutant $S_{3',4'}$	−	Both alleles active in pollen
$S_{3,6}$ × " $S_{3',4'}$	+	$S_{4'}$ pollen functions
$S_{4,5}$ × " $S_{3',4'}$	+	$S_{3'}$ pollen functions
Mutant $S_{3',4'}$ × Parent $S_{3,4}$	+	$S_{3'}$ or $S_{4'}$ not active in style

The seedling is self-fertile, which shows that one of the S alleles is not operating in either the pollen or style or both. The seedling fails as male on the parent, $S_{3,4}$, and is compatible on $S_{3,6}$ and $S_{4,5}$, which proves that it is a heterozygote and that both $S_{3'}$ and $S_{4'}$ are fully active in the pollen. The incompatibility of the seedling when crossed with the parent $S_{3,4}$ shows that one of the alleles is not operating in the style.

There seems to us to be only one way in which this mutation could have arisen. A simultaneous mutation was induced in the two parts of the S complex: the 'stylar' mutation remained permanent and the 'pollen' mutation—which must have occurred to have given compatibility to the original pollen grain which begot the seedling—reverted to normal. The simultaneous occurrence after X-rays of a permanent 'stylar' mutation and a revertible 'pollen' mutation would require a high degree of improbability if their causes were independent, as they would be if the revertible changes were not genuine gene mutations.

The different post-mutational histories of the two parts of the S complex show that not only are the two parts independent in their mutation but also in their reversion.

The evidence of La Cour and Rutishauser[3] on sub-chromatid breaks, which is the cytological basis of the theory of revertible mutations, shows that they do not occur in the resting nucleus or at metaphase. It is significant that the revertible mutation in *Prunus* occurred with irradiations given at a period which would include the prophase stage. All the permanent 'complete' mutations were induced by treatments given in the resting stage and not including any prophase nuclei.

The complementary nature of the cytological and genetical evidence not only confirms the link between chromosome breakage and gene mutation but upholds the theory that revertible mutation is due to a loss of a proportion of the polypeptide chains of the gene followed by recovery of the unaffected remainder.

Chromosome Breakage Experiments with Endosperm: Sub-chromatid Breakage

ERRORS in chromosome separation at anaphase appear in the interval following X-raying which follows the period when the chromosomes are susceptible to breakage[1]. Similar errors appear with various chemicals, but not always in association with the later occurrence of chromosome breakage[2-5], and with heterochromatic segments after cold treatment[6].

Earlier accounts give these errors in two forms—intercalary adhesion and terminal attachment. Typical of many intercalary types is the chiasma-like structure at the point of attachment. Levan[7] noted that the error was scarcely attributable to stickiness, since breakage of the bridge was generally away from the point of attachment. Darlington[8] invoked two-plane splitting of a monid structure to explain similar

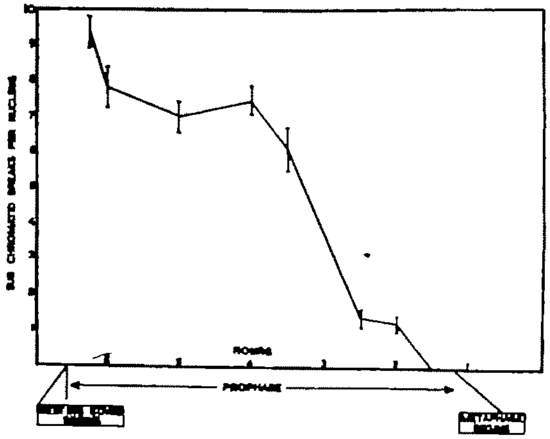

Fig. 1. Graph showing the distribution of sub-chromatid breaks deduced from the point effects at anaphase in *Scilla sibirica* endosperm (3x, x = 12) after a dose of 54 r. The onset of complete breakage at 6½ hr. (seen in metaphases) limits the point effect to a prophase origin

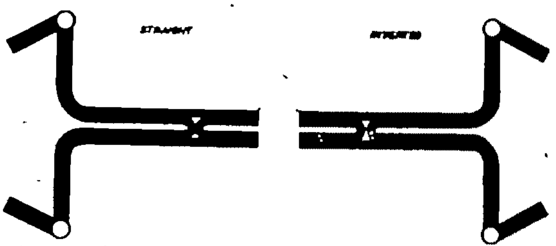

Fig. 2. Diagram illustrating the effect of breakage and two possible kinds of reunion of half-chromatids, to give homologous intercalary point effects. *Note*: We believe, however, that smaller sub-units or 'monids' can be involved. The later early anaphase condition is depicted for simplicity. On the sub-chromatid theory one point effect is derived from two sub-chromatid breaks

errors at meiosis. D'Amato[5] proposed isochromatid breakage with reunion of four broken ends at one point. Neither of the last two views is compatible with the following evidence obtained from *Scilla* endosperm.

Fixations were made at half-hourly intervals, 1–6 hr. following a radiation dose of 54 r. (temperature 18° C. throughout).

The onset and frequency of sub-chromatid breaks as deduced from the errors observed per anaphase nucleus are shown in Fig. 1. The complete mitotic cycle takes approximately 48 hr. A 6½-hr. fixation in endosperm undergoing wave mitosis showed metaphases with chromatid breakage (*B'*) and anaphases with adhesions alone. Both primary and secondary effects therefore most likely overlap.

Close scrutiny of affected anaphases reveals configurations more complex than any hitherto described. These involve associations at non-homologous loci and can be classified as intrachromatid and interchromatid. The first gives loop structures. The last, which can involve sister or non-sisters, gives configurations with unequal arms distal to the point of union. These aberrations, together with the chiasma-like structure evident in intercalary configurations, provide the clue to the origin of the point effect.

Such points, as Darlington[8] assumed, clearly involve sub-chromatids, a condition being produced by breakage and reunion, simulating crossing-over, as inferred in Fig. 2 (cf. Fig. 3). The origin of configurations involving non-homologous loci then becomes clear. They result from sub-chromatid breakage and reunion in coiled and overlapping chromatids at prophase (Fig. 4).

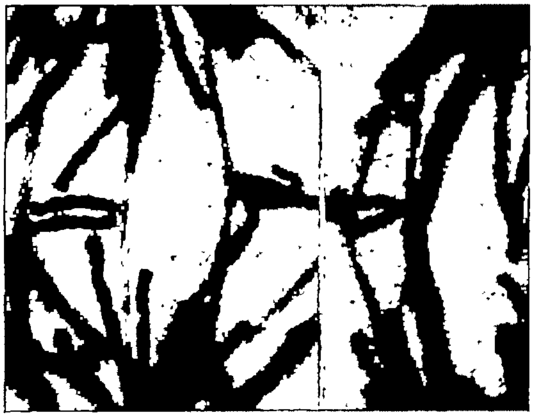

Fig. 3. Microphotographs of anaphase nuclei from *Scilla sibirica* endosperm five hours after 54 r. (× 900). The left-hand nucleus shows two intercalary point effects. Note sub-chromatid structure and evidence of inverted union (cf. Fig. 2). On the right, a part nucleus with homologous interchromatid and non-homologous intrachromatid point effects in one chromosome (cf. Fig. 4)

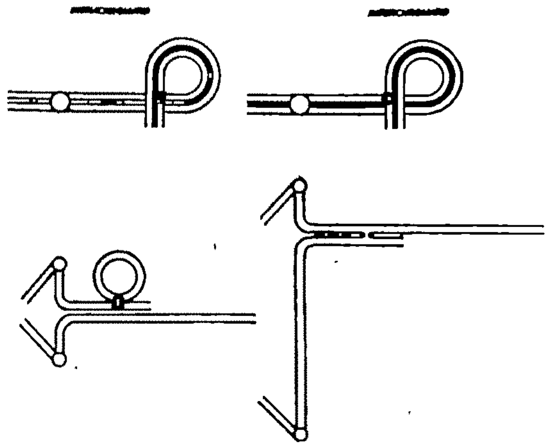

Fig. 4. Diagram illustrating the origin of point effects at non-homologous loci through coiling in prophase chromosomes. The later early anaphase condition is depicted for simplicity

The idea of partial chromatid breakage is not new. The supporting evidence has generally, however, been unclear and indecisive[9,10]. Two observations are in line with ours. They agree in the time at which, probably, sub-chromatid breakage universally occurs with treatment, namely, at prophase. Thus Swanson[11] obtained partial chromatid breakage with irradiation of generative nuclei in *Tradescantia* pollen, and Slizynski[12], likewise, in salivary gland nuclei irradiated earlier in ontogeny.

Apparently the centromere, although passive to chromosome breakage in the resting nucleus, limits sub-chromatid breakage at prophase. Rees[13] obtained evidence of centromere interference in the position of point effects. In our material, also, point effects are extremely rare near the centromere. We can but conjecture if this is also true of thoroughgoing chromatid breakage.

The main conclusion to be drawn from our *Scilla* experiments is that regularly sub-chromatid breaks are induced by treatment during prophase but not during the resting stage and metaphase.

Finally, there is no denying the probability of a causal relationship between sub-chromatid breakage and delayed mutation. It is significant that Lewis and Crowe[14] obtained a revertible mutation in *Prunus* with irradiation of prophase: only stable 'complete' mutations occurred with treatment of the resting stage. Likewise, it is significant that mosaics never occur in *Drosophila* with X-ray treatment of the sperm.

A fuller account of these observations is being given elsewhere.

A New Method of Estimating the Survival-Rate of Anopheline Mosquitoes in Nature

THE sporozoite infection-rate of anopheline vectors of malaria dissected upon the day of capture depends upon, among other variables, the proportion which have survived long enough for the completion of the extrinsic cycle of the malaria parasite in them. If wild-caught mosquitoes are kept alive after capture for a period equal to that of the extrinsic cycle, the sporozoite-rate found at the end of this period would represent the proportion with any infection, however immature, at the time of capture. The ratio between the immediate and delayed sporozoite-rates is directly proportional to the chance of survival of the mosquitoes from the time that they receive an infective feed until sporozoites can be found in the salivary glands. The other variables influencing the sporozoite-rate, such as the infectivity of the population, can be ignored as they have the same effect on the two rates. The pattern of mosquito mortality is thought to be geometric, all age-groups being on average exposed to the same risk of mortality[1], so that it is possible to establish a simple mathematical relationship between the daily chance of survival and the ratio between the sporozoite-rates, where p = the probability of a mosquito surviving through one day, and n = period in days for completion of the extrinsic cycle in the mosquito (1 is subtracted from this as the mosquitoes are on average at least one day old at the time of the infective blood meal):

$$\frac{p^{n-1}}{1} = \frac{\text{Immediate sporozoite-rate}}{\text{Delayed sporozoite-rate}}$$

$$\text{or } \log p = \frac{\log \text{ratio}}{n-1}$$

whence p can readily be calculated.

We have recently made observations in a coastal area of tropical East Africa where *Anopheles gambiae* and *Anopheles funestus* are the principal vectors of malaria. The results of dissections made over a period of three months (September–December 1952) are summarized in the accompanying table. The delayed sporozoite-rate is based on dissections done from thirteen days onwards after capture, as direct observations of the period of the extrinsic cycle showed that thirteen days (n) was the time required for the appearance of sporozoites of *Plasmodium falciparum*, the predominant parasite, under the prevailing climatic conditions.

The figures show that in this area the average mortality of the *A. gambiae* population was of the order of 7 per cent per day, and that of the *A. funestus* population of the order of 8 per cent. Such low values are consistent with the well-known efficiency of these species as malaria vectors and the intensity of the malaria caused by them. The suggestion that *A. funestus* has a higher mortality-rate than *A. gambiae* was confirmed by observing the mortalities among mosquitoes kept in cages.

	Immediate dissections		Delayed dissections		Ratio: immediate/delayed	Calculated value of p
	Total dissected	Sporozoite-rate (per cent)	Total dissected	Sporozoite-rate (per cent)		
A. gambiae	700	4·7 ± 0·6	382	11·0 ± 2·6	0·43	0·93
A. funestus	1,119	3·4 ± 0·3	593	9·6 ± 1·5	0·35	0·92

An estimate of the natural mortality of vector species, together with other malariological indices, is a prerequisite of the planning of malaria control schemes by imagocidal methods. There is a possibility that the principle of this method of estimating mortality may be applicable to other insects which act as hosts to parasites with a known developmental cycle.

Abnormal Embryonic Development in *Drosophila* Induced by Ultrasonic Treatment

WE have found that treatment with ultrasonics of eggs of *Drosophila melanogaster* can induce abnormal embryonic development, and the method provides a tool for use in experimental embryology. Ultrasonic intensities insufficiently great to cause the disruptive effects of cavitation and the associated chemical effects may yet induce streaming movements within the egg so that nuclei, cytoplasm and yolk are left in unusual positions. Abnormal development may then follow.

Large numbers of eggs at the same developmental stage were treated on agar disks in a water medium under controlled conditions of uniform ultrasonic intensity, at a frequency of 1 Mc./s., at room temperature. The apparatus has been described elsewhere[1]. Subsequent development was investigated using permanent stained serial sections fixed at intervals up to 20 hours after treatment. The mode of action of the ultrasonics was confirmed by visual microscopical observations made on dechorionated eggs during treatment, using an ultrasonic stage generator similar to that used by Harvey, E. N., Harvey, E. B., and Loomis, A. L.[2], when they observed the whirling of chloroplasts by ultrasonics in leaves of *Elodea*.

Embryos treated at the syncytial blastoderm stage (two hours after laying at 25° C.) were usually affected in the posterior region. The pole cells were most easily set in motion; they rotated rapidly and created a local vortex into which blastoderm nuclei were drawn, followed by yolk and cytoplasm from the interior of the embryo as the disturbance spread (Fig. 1). After treatment at ultrasonic intensities of 0·3–0·5 watts/cm.^{2} for 30 seconds at the syncytial blastoderm stage, 91 embryos were incubated for a further 10–18 hours at 25° C., and then fixed for sectioning. Twenty-three embryos showed normal development. Ten showed only slight irregularities such as abnormal segmentation or absence of gonads. Twenty-three exhibited abnormal spatial relationships between organs or showed absence of certain organs, the involution of the head and the hypodermis being most markedly affected (Fig. 2); no supernumerary organs were found. Eighteen showed no organogenesis but differentiation of cells occurred (for example, the nervous system was differentiated into ganglion and fibres,

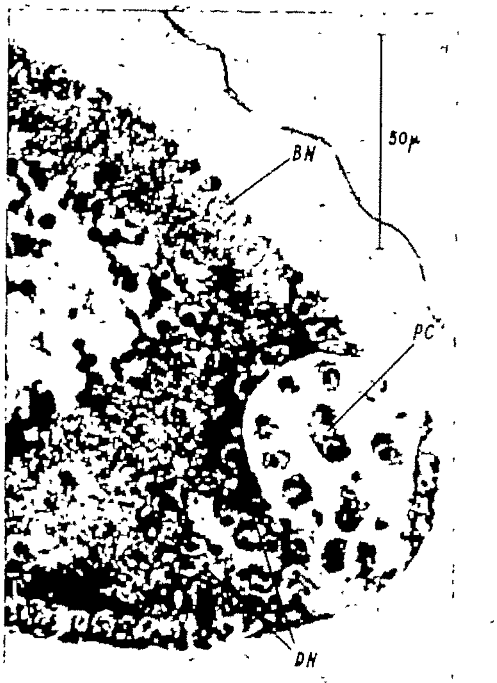

Fig. 1. Posterior region of embryo immediately after treatment at syncytial blastoderm stage. *BN*, blastoderm nuclei; *DN*, displaced blastoderm nuclei; *PC*, pole cell vortex

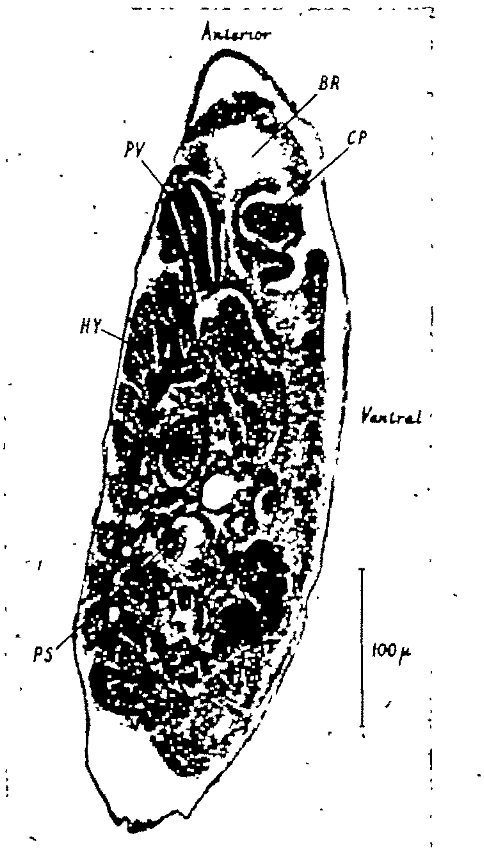

Fig. 2. Longitudinal section of abnormal 20-hr. embryo treated at syncytial blastoderm stage. *BR*, brain (displaced); *CP*, cephalopharyngeal apparatus (displaced); *HY*, hypodermis (note the absence of hypodermis anteriorly and ventrally); *PS*, posterior spiracle (displaced); *PV*, proventriculus (displaced)

and elongation of muscle cells sometimes took place without fusion). Ten showed proliferation of cells without differentiation into cell types, and seven failed to develop. Similar treatments at pre-blastoderm stages were either followed by complete recovery and normal development, or by little or no further development. Our results confirm the observations of delayed mortality made by Fritz-Niggli[3]. For any given dose of ultrasonics, lethality is at a maximum when the treatment is carried out at the syncytial blastoderm stage.

The use of ultrasonics in insect embryology has certain advantages over other experimental methods. No materials are removed from the egg as they are in pricking experiments, and no material need be destroyed by the treatment as it is when ultra-violet radiation or cauterization is applied to selected regions.

This work is in progress and will be reported fully elsewhere. One of us (S. J. C.) was the recipient of the Dorothy Bridgman Atkinson Fellowship, given by the American Association of University Women, and the work received financial support from the Agricultural Research Council. We are indebted to Prof. C. H. Waddington for discussion and encouragement.

Avian Medullary Bone

Since the report by Kyes and Potter[1] that the marrow cavities of the tibia and femora of female pigeons become filled with endosteal bone during the laying cycle, this phenomenon has been the subject of intensive study in the sparrow[2], duck[3] and domestic fowl[4,5], as well as in the pigeon[6,7]. This highly labile medullary bone appears to serve as a readily available store of calcium for the calcification of the egg shell. It has been studied almost exclusively in the long bones of the legs, though Zondek[8] found it also in the vertebral column of young cockerels after treatment with oestrogen.

In an experiment with eight laying pullets we have found that medullary bone is far less restricted in its occurrence than has been supposed. It is present in all bones, although the skull, humerus, metacarpals, wing digits, metatarsi and toes contain only small amounts. Medullary bone is soft and powdery and may readily be separated from cortical and cancellous bone either by scraping or by careful grinding and sieving. The following table gives the

	Dry fat-free bone weights (gm.) Total	Medullary	% Medullary
Tibia	12 96	1 61	12·4
Femora	10 60	2·29	21·6
Ilia, ischia and pubis	8·86	1·85	20·8
Sternum	6·66	1·03	15·5
Ribs	4·02	1·17	29·2
Ulnae	4·02	0·16	4·0
Toes	3·63	0·05	1·3
Scapulae	1·99	0·32	16·1
Total skeleton	95·50	11·21	11·7

amount of medullary bone present in certain bones from a typical pullet fed a standard laying ration and killed immediately after laying her third egg.

Sex Chromosomes of *Ranatra elongata*

IN all the members of the family Nepidæ (Hemiptera–Heteroptera) investigated so far from the above point of view, the diploid number of chromosomes in the male germ-cells has been reported to be 43–38 autosomes and 5 sex chromosomes[1–4]. Chickering's[5] account of the chromosomes of *Ranatra linearis*, according to which the spermatogonia of this insect are of two kinds, one type possessing 40, and the other 48–50 chromosomes, has been shown to be erroneous by Steopoe[2].

Recently, we have been engaged in the investigation of the chromosomes of the male germ-cells of *Ranatra elongata*, collected from the McPherson Lake, Allahabad, and have discovered to our surprise that the sex-determining chromosomes of this species consist of four elements, $X_1X_2X_3Y$, and not of five elements, $X_1X_2X_3X_4Y$, as reported by Steopoe[3] for *R. linearis* and more recently by Dass[4] for *R. elongata* of Bangalore. According to Steopoe, there are, at the first meiotic metaphase, 19 autosomal bivalents and 5 sex chromosomes in *R. linearis*. We find, on the other hand, in Allahabad specimens of *R. elongata*, 19 autosomal bivalents and 4 sex chromosomes ($X_1X_2X_3Y$) at the first meiotic metaphase. The partners of the bivalents separate normally, and all the sex chromosomes divide at this stage (the first metaphase). Each pole thus receives 4 sex chromosomes and 19 autosomes. The interkinesis is completely abolished. At the second metaphase there are 19 autosomes and 4 sex chromosomes, the latter forming a pseudo-quadrivalent and becoming arranged on the equator of the spindle in such a way that the three X-chromosomes are placed towards one pole and the Y towards the other. The 19 autosomes divide and the 3 X-chromosomes and the Y-chromosome move to the opposite poles, so that at the end of the second anaphase there are 19 autosomes and 3 X-chromosomes at one pole and 19 autosomes and the Y-chromosome at the other. The two types of spermatids thus possess 22 and 20 chromosomes respectively and not 23 and 20 elements, as shown by Dass[4] in Bangalore specimens of *R. elongata* and Steopoe[3] in *R. linearis*. Consistently with this, we find 42 chromosomes at the spermatogonial metaphase, and not 43, as reported by Dass[4]. The Allahabad specimens of *R. elongata* differ from the other members of the family Nepidæ by the loss of a single X-chromosome.

As reported by Steopoe[3], the X-chromosomes are very small and the Y is large, all the sex chromosomes occupying a central position in the polar view of the first metaphase, being surrounded by a ring of autosomes. The sex chromosomes are markedly heteropycnotic. In the spermatid nuclei they form a single lump of deeply staining matter, whereas the autosomes are no longer stainable.

Resistance to the Maize Rust, *Puccinia polysora* Underw.

SINCE 1950, epidemics have been reported of a rust disease of maize due to *Puccinia polysora* Underw. which is new to West Africa[1]. The identity of this rust has been confirmed by Stanton and Cammack[2] by the discovery of the teleutospore phase in Nigeria which agrees with the description by Cummins[3].

Hitherto the most satisfactory method of combating the cereal rusts has been by the introduction of genes for resistance to these diseases. This is so in spite of the ever-changing racial pattern of these rusts. A search was therefore made by us for sources of resistance to *Puccinia polysora*, and a wide range of material, assembled by the Department of Agriculture, Nigeria, has been tested in the field and under controlled conditions using methods similar to those of Manners[4]. The material tested may be classified as follows:

Sources of varieties	Number	Resistance
West Africa	31	No resistance found.
East Africa	7	
South Africa	2	
India	18	No resistance found.
Ceylon	7	
Malaya	2	
United States	20	Of variable resistance.
Mexico	22	Several tolerant and highly resistant varieties.
Caribbean	3	
Venezuela	2	

It is clear that several sources of resistance are available, and, as some of the resistant varieties approach agronomic suitability to West African conditions, little difficulty is likely to occur in their adaptation for West Africa. The location of the source of resistance is interesting in that it provides yet another example to support Vavilov's[5] theory of the centres of origin of cultivated plants, of their associated pathogens which have evolved with them, and of the evolution of genes for pathogen resistance. Preliminary crosses between resistant and susceptible varieties indicate discrete segregation, resistance being dominant to susceptibility, as in the case of resistance to *P. sorghi* Schw.[6]. Several gradations of susceptibility are detectable.

Stage	Degree of susceptibility	Appearance
0	Host immune	No uredosori developed. Hypersensitive flecks present, but no hyphae in host tissues.
1	Host very resistant	Uredosori abortive and isolated, surrounded by sharply defined necrotic areas.
2	Host moderately resistant	Uredosori small and isolated. Surrounded by necrotic rings within a green island, which may be proximally chlorotic.
3	Host moderately susceptible	Uredosori medium-sized. Chlorotic patches present.
4	Host very susceptible	Uredosori large, numerous, in extensive clusters. Large chlorotic areas.

Of the imported material so far received, five varieties from Mexico show promise of suitability as sources of resistance for the synthesis of varieties adapted to West African conditions.

Effects of Close Spacing on the Growth of Garden Beet

THAT close spacing restricts the growth of most plants is so obvious as not to require experimental proof. Horticulturally, this is a problem of considerable interest because it means that attempts to increase yields by increasing the plant density are not successful. With some crops 'yield' may bear no close relation to total growth, but this is not so for most root vegetables. Further, with these crops, it is possible to determine for any locality the population-range which can be depended on to give the maximum yield of salable roots. Thus on a fertile loam in Cheshire maximum yields of long beet are assured if the plant population lies between 70,000 and 135,000 per acre. Corresponding figures for globe beet are 110,000 and 150,000 with a possible extension of the latter figure. Within these population-ranges total yields may change slightly; but the yields of salable roots (after rejection of small ones) remain constant. There is almost and sometimes quite complete dependence of root size on available space. Thus in one experiment on globe beet, plants allotted 90 sq. in. each had a mean root weight of 10·88 oz. A reduction in the space available per plant by 60 per cent reduced the mean root weight by 58·4 per cent. Why the closely spaced plants should be so small is not clear. In our experiments, even at the closest spacings employed, adjacent plants do not suffer deformation by mutual pressure. Neither have we evidence that it would be harmful if they did. Clearly, the restriction in size which results from close spacing is not due simply to lack of 'room'. Three factors of the environment, competition for which may occur with closely spaced plants, are light, water and mineral nutrients (including nitrogen).

With garden beet we may assume that the ratio of root weight to top, that is, lamina plus petiole, will give an approximate measure of the photosynthetic efficiency of the leaves. It will be approximate because top weight includes petioles the photosynthetic activity of which is likely to be low in relation to their weight, and the spacing may affect the period of active leaf production. Always we find that when the space available per plant is increased, the weight of tops produced per plant increases (but never so markedly as the increase in available space) and the root/top ratio increases. In single experiments it is not always possible to show that the increase in the root to top ratio is statistically significant; consideration of all the available data, however, leaves one in no doubt as to the reality of the increase. But this effect was appreciable only in 1948 and 1950 and was slight in 1949. In 1949, July and August provided 373 hr. of bright sunshine. Corresponding figures for 1948 and 1950 were 259 and 307 hr. Figures for August only are for the years 1948, 1949 and 1950, 89, 192 and 138 hr. respectively. This does suggest that in relatively sunless years at least, mutual shading of the closely spaced plants may be important, and by restricting photosynthesis, may reduce the flow of assimilates to the storage organ. There is certainly the possibility of this because decreases in available space per plant do not result in proportionate decreases in the weight of tops per plant, so that the weight of tops per unit area of ground is greatest when the plants are closely spaced. Alterations in the root to top ratio induced by spacing changes are, however, never so great as are the changes in the weight of tops per plant. It appears, therefore, that root weight is more dependent on or at least related to leaf weight than to 'leaf efficiency' and that competition for light can play only a small part in restricting the growth of the closely spaced plants.

There is no evidence that competition for water could explain the results obtained. In 1948, July and August provided 7·54 in. of rain (following a rainfall of 4·52 in. in June). In 1950, in only one week subsequent to July 1 was the rainfall less than 0·50 in., and the total for July and August was 6·65 in. Rainfall in 1949 was less abundant at 4·11 in. for July and August; but even so no crops showed any of the signs of distress indicative of a water shortage.

Analyses of leaves from eight of these experiments have failed to reveal any statistically significant effect of close spacing on the contents of nitrogen, potassium, calcium or phosphorus in the leaves when the plants are normally manured. In one experiment, close spacing reduced the nitrogen content of the leaves when the plants received no manure, so that there was a significant positive correlation between nitrogen content of the leaves and root weight, and both were dependent upon the space available per plant. When manured, the nitrogen content of the leaves was not affected by the spacing, but the dependence of root weight on available space persisted. This is the result always obtained on manured plots.

It appears, therefore, that while in the absence of manuring close spacing may result in competition for nitrogen, and that competition for light may be operative, the major effects of close spacing on the growth of normally manured plants cannot be explained solely in terms of competition for water, light or the major nutrient elements.

Influence of Rhizosphere Micro-organisms on the Virulence of *Rhizobium trifolii*

THE increasing interest which has been shown in the interactions of *Rhizobia* with other micro-organisms of the indigenous population of the soil has been reflected in the growing list of organisms which have been found to be inhibitory or antagonistic to their growth in various media. The reviews by Casas-Campillo[1] and Abdel-Ghaffar and Allen[2] emphasize the prominent role of Actinomycetes in such antibioses, but indicate that quite a wide range of bacteria may produce significant effects also. It is noteworthy that, though much attention has been paid to antagonistic organisms, relatively little has been reported of micro-organisms stimulating the activity of *Rhizobia*. Krasilnikov and Korenyako[3] found that a number of non-sporing bacteria of the genera *Pseudomonas* and *Achromobacter* introduced into the rhizosphere of the leguminous host induced an increase in the numbers of *Rhizobia* per gram of rhizosphere soil, and that as a consequence the number of nodules per plant showed an increase and the time taken for nodules to appear was shortened. Such bacteria were termed 'activators' in contrast to types which were inhibitors, or to others which were without effect. These workers advocate that seed should be inoculated with mixed cultures of *Rhizobia* plus activators on the basis of their findings of increased herbage yield and seed set of beans, lucerne and lupins.

While investigating the plant–rhizobial relationships between *Trifolium subterraneum* (subterranean clover) and strains of *Rhizobium trifolii* in pot experiments, it was noticed that one strain (No. 44) gave an ineffective reaction as measured by plant growth in sterilized soils; but in similar soils not subject to heat treatment, an effective reaction was obtained with no evidence of nitrogen starvation symptoms.

Examination of the root systems showed that in sterilized soils nodulation was scanty and restricted to a few small, round clumps of confluent, clavate nodules. In the non-sterile soils, nodulation was unrestricted and much more profuse in quantity; but of the same characteristic morphology. Occasional nodules produced from infection by the indigenous *Rhizobia* of these soils were large and flabellate, and readily distinguished from those produced by the inoculated organism. It was further noticed that root growth in non-sterile soils showed varying degrees of discoloration and sloughing of fragments. Plating out surface sterilized (alcohol-peroxide) pieces of roots on suitable nutrient agars revealed infection by a range of fungi and bacteria frequently found in association with plant roots. The fungi most frequently encountered were members of the genera *Fusarium*, *Trichoderma*, *Penicillium*, *Aspergillus* and various dark-coloured Dematiaceæ. The range of bacteria found was diverse and included both sporing and non-sporing types typical of zymogenous activity in the proximity of plant roots.

Surface-sterilized seeds of subterranean clover were germinated on water-agar, the testa removed, embryos re-sterilized and transferred for aseptic growth on slopes of a mineral salts–soft agar medium free from sources of nitrogen and carbohydrate, but which was capable of adequately providing other major and trace nutrient elements. The test-tubes containing the plants were held in the glass-house until the first trifoliate leaf had unfolded, and then inoculated with a suspension of organisms grown on agar slopes. The accompanying table shows the comparison in nodule numbers for two strains, Nos. 44 and 430, of *Rh. trifolii* with a nil control series from which the *Rhizobia* have been withheld. Strain 430 is an effective strain with nodulation little affected by the presence of the other rhizosphere fungi and bacteria applied with the inoculum. Strain 44 is poorly virulent, and forms few nodules on subterranean clover in pure culture. In the presence of some fungi and bacteria its ability to produce successful infection of the root system is enhanced, and nodulation improves to give an effective reaction.

NODULE COUNTS PER PLANT FOR SUBTERRANEAN CLOVER GROWN IN TEST-TUBES AND SIMULTANEOUSLY INOCULATED WITH STRAINS OF *Rh. trifolii* AND OTHER RHIZOSPHERE FUNGI AND BACTERIA. MEANS OF THREE REPLICATE TUBES EACH WITH TWO PLANTS PER TUBE. STANDARD ERROR OF TREATMENT MEAN ± 2·4

	Nil control	*Rh. trifolii* strain 44	*Rh. trifolii* strain 430
Nil control	0	2·3	12
Fungus			
1013 (*Fusarium*)	0	1·7	0
1015 (*Sclerotinia*)	0	0	1
1017 (Dematiaceæ)	0	7·7	0
1018 (Dematiaceæ)	0	8·7	13
1019 (*Trichoderma*)	0	3·0	12
M (*Hormodendrum*)	0	0	12
N (*Hormodendrum*)	0	0	6
O (*Fusarium*)	0	0	14
Bacteria			
1506	0	0	13
1507	0	0	13
1508	0	12	14
1509	0	14	15
1510	0	13	11
1511	0	12	9
1512	0	14	18

The presence of a parasitic organism capable of rapidly killing the plant completely inhibits nodule formation as in the case of *Fusarium* 1013 and *Sclerotinia* 1015; where the degree of parasitism is not so great, but invasion of root tissues takes place with extensive local root rots, as in the case of the dematiaceous fungus 1017 and *Hormodendrum N*, the nodulation with *Rh. trifolii* strain 430 shows a reduction probably due to impaired functions of the metabolism of the plant rather than direct antagonism of the fungus to the *Rhizobia*. Some strains of fungi and bacteria were capable of stimulating the poorly virulent strain 44, but others produced no effect. Where stimulation is sufficient to produce an adequate volume of nodular tissue, the plant reaction is effective. Strain 44 may thus be regarded as a strain efficient in nitrogen fixation but of poor virulence. Its apparent ineffective reaction in sterilized soils is not necessarily reproduced in natural soils under non-sterile conditions where the presence of a wide range of soil organisms may be capable of this non-specific stimulation of virulence in the rhizosphere. The question arises as to whether such poorly virulent strains of *Rhizobia* may be safely used in the artificial inoculation of legume seeds on a commercial basis, assuming that stimulation will be adequate in the rhizosphere, or whether in testing strains of *Rhizobia* for such purposes, care should be taken to select only highly virulent types which are efficient in nitrogen fixation, or whether to add the so-called 'activators' as suggested by Krasilnikov and Korenyako[3]. Furthermore, one wonders whether many of the cases of reports of large numbers of strains of *Rhizobia* of inefficient nitrogen fixation found in soils under natural conditions may not have been made on the basis of poorly virulent strains giving apparently ineffective plant reactions when tested under sterile conditions. Despite such claims, there appear in the literature very few cases of failure of legumes which can be definitely ascribed to a predominant nodulation by ineffective strains of indigenous *Rhizobia*.

These observations form part of a series of investigations being undertaken on the ecological relationships of *Rh. trifolii* and its importance as a factor in the establishment of subterranean clover in soils of low fertility, the results of which will be reported in greater detail elsewhere.

Structure of Poly-D-glutamic Acid Isolated from Capsulated Strains of *B. anthracis*

We have already shown[1,2] that the poly-D-glutamic acid of molecular weight 6,400–9,000 which *B. subtilis* secretes into the culture medium contains γ-glutamyl links (I, $R = COOH$) in such predominance that few α-glutamyl links (III, $R = COOH$) can be present in the substance. This statement is based on the observation that in the acid hydrolysate of the polyamine derivative (I, $R = NH_2$) prepared from the polypeptide, by Curtius degradation of the polyhydrazide (I, $R = CON_2H_3$) or by Hofmann degradation of the polyamide (I, $R = CONH_2$), only β-formylpropionic acid (II) appears in quantities easily assayable by preparative methods, and no α.γ-diaminobutyric acid was found to be present. Control experiments with synthetic α-polyglutamic acid, on the other hand, readily gave α.γ-diaminobutyric acid (IV) on acid hydrolysis of the degradation product.

Hanby and Rydon[3] came to the reverse conclusion regarding the predominating type of the glutamyl linkages with poly-D-glutamic acid separated from capsulated strains of *B. anthracis*. Since Ivánovics and Bruckner[4] found no difference by chemical and serological reactions between the polyglutamic acids of identical molecular weight (6,400–7,100) isolated from the two species of bacilli, extension of the above degradation to poly-D-glutamic acid of *B. anthracis* appeared desirable.

For the preparation of the polypeptide, a non-sporing capsulated *B. anthracis* strain (No. *A* 71 *T*) of low virulence was used, which appears to be identical as regards its morphological and cultivation characteristics with the cultures furnished by White[5] for Hanby and Rydon's experiments. This strain was raised from a capsulated strain (No. *A* 71) of high virulence which was inoculated into horse serum, then kept for three weeks at 37° and used afterwards for isolation of the strain in question. Isolation of the crude polypeptide from agar cultures of this strain followed strictly Hanby and Rydon's method[3]. This substance was dried *in vacuo* at room temperature, then esterified with methyl alcohol by addition of acetyl chloride. The crude ester was now repeatedly fractionated from methanol by precipitation with increasing quantities of ether. After stepwise extraction with cold water there remained an undissolved fraction which contained no ash and had the average molecular weight of 45,000–53,000 (van Slyke), which is in the order shown by specimens described by Hanby and Rydon. Analysis demonstrated about 75 per cent esterification of the carboxyl groups. The slight solubility in water appears to be due to the presence of the remaining free carboxyl groups. In degradation, both of the polyhydrazide and polyamide prepared from the polyester, only β-formylpropionic acid (II) could be detected by preparative methods but no α.γ-diaminobutyric acid (IV). This suggests that also in the high molecular-weight poly-D-glutamic acid of *B. anthracis* it is the γ-glutamyl link which is the predominant type.

Details of this work will be published elsewhere.

Intracellular Distribution of Rhodanese in Cardiac Muscle

The distribution of enzymes within animal tissues has been studied most extensively in the case of liver. Particular interest has centred round the large granules (mitochondria), which have been found to contain the components of the cytochrome system, to catalyse the oxidation of all the citric acid cycle intermediates and the oxidation of fatty acids, and to carry out oxidative phosphorylation[1]. Recent work on cardiac muscle has shown that the particulate fraction (sarcosomes[2]) has a similar complement of respiratory enzymes and co-enzymes[2,3]; and there has been a tendency for sarcosomes to be considered identical with mitochondria. However, a large number of other enzymes are known to be associated with liver mitochondria, and it was of interest to investigate the distribution of one of these non-respiratory enzymes in cardiac muscle.

The enzyme chosen for study was rhodanese, which catalyses the reaction,

$$HCN + Na_2S_2O_3 \rightarrow HCNS + Na_2SO_3.$$

Most of the rhodanese activity of liver has been found in the mitochondria[4].

Calf cardiac muscle was homogenized in 0·88 *M* sucrose[5] and three fractions were obtained by differential centrifugation: (*a*) myofibrillar-

INTRACELLULAR DISTRIBUTION OF RHODANESE

	Liver (Ludewig and Chanutin)	Cardiac muscle (Moyle)		
Fraction	Total activity (per cent)	Total activity (per cent)	Total dry wt. (per cent)	Specific activity
Homogenate	100	100	100	1
(*a*) Residue	15	44		
(*b*) Large particles	62	2	9·3	0·2
(*c*) Supernatant	7	56		
a + *b* + *c*	84	102		

nuclear residue, (*b*) sarcosomes and (*c*) sarcoplasm. Rhodanese activity was estimated by the method of Cosby and Sumner[6]. A comparison of the activity of the homogenate and the tissue fractions showed that the sarcosomes contained no rhodanese, the total activity of the muscle being only about 10 per cent that of liver (per unit weight).

Cleland and Slater[2] have reported a parallel situation in the distribution of myokinase, which occurs in the sarcoplasm of cardiac muscle but in the mitochondria of liver[7].

So, although the 'large granules' from liver and heart muscle show similarity in being the site of respiratory enzyme systems, they are not completely identical units differing only slightly in morphology from tissue to tissue. In their diverse non-respiratory functions they may take very different roles in the metabolism of their respective tissues.

I wish to thank Dr. M. Dixon for valuable advice, and the Medical Research Council for a grant.

Activation of Fumaric Hydrogenase by Ferrous Ions

FISCHER *et al.*[1] described an enzyme from yeast which catalyses the reduction of fumarate to succinate by leuco-dyestuffs. They showed that the coenzyme is flavine adenine dinucleotide.

It has now been found that addition of flavine adenine dinucleotide does not fully restore the activity of this enzyme after dialysis and adsorption on alumina Cγ, but that addition of ferrous ions is also necessary.

Thunberg tubes contained: 0·5 ml. 0·05 *M* phosphate buffer *p*H 7·4 and 1 ml. 0·03 *M* fumarate. In stopper: 0·5 ml. 0·0002 *M* janus green reduced with 0·2 mgm. hydrosulphite. Gas, nitrogen.

ACTIVATION OF FUMARIC HYDROGENASE

Additions	Oxidation time (min.)
Nil	> 25
Fe^{++}	> 25
Enzyme	10½
Enzyme + Fe^{++}	1½

Additions: 1 ml. enzyme (dialysed in the presence of flavine adenine dinucleotide); 0·2 ml. 0·01 *M* $FeSO_4$. Other metals such as Mn^{++} are ineffective. Keilin–Hartree preparations of succinic dehydrogenase from heart muscle also lose activity on dialysis; addition of ferrous ions enables the reduction of fumarate to take place. It would appear, therefore, that ferrous ions are required for electron transfer in succinate–fumarate systems.

Chromaffin Bodies of Various Species of Dogfish

IN lower vertebrates, structures homologous to the adrenal gland of higher vertebrates remain separated throughout life. In the dogfish, for example, an unpaired inter-renal body representing the adrenal cortex is quite separate from the chromaffin bodies or rudimentary adrenal medulla. Extracts of each component can therefore be made without contamination by the other part.

Since workers in both our departments are interested in the biosynthesis of adrenaline, we have investigated by chromatographic and biological methods the amines present in the chromaffin bodies of *Scylliorhinus canicula* and *stellaris* (in Bari), *Squalus acanthias* and *Mustelis canis* (in Dundee) and *Torpedo marmorata* (in both Bari and Dundee). Our pooled results are shown in the accompanying table. Large quantities of adrenaline and noradrenaline are contained in these extracts; but hydroxytyramine, dihydroxyphenylalanine, dihydroxyphenylserine, tyramine and octopamine (*p*-norsynephrine) are not present in detectable amounts. Concentrated extracts of the livers, kidneys, intestinal tract, and inter-renal bodies of these dogfish species do not contain significant amounts of any of the seven substances mentioned.

AMINES (μGM./GM.) PRESENT IN THE CHROMAFFIN BODIES OF DOGFISH SPECIES

Species	Adrenaline	Noradrenaline	Noradrenaline (per cent in total)
Squalus acanthias	900	2,400	73
Mustelis canis	1,000	2,200	69
Scylliorhinus canicula	1,150	2,200	66
Scylliorhinus stellaris	850	1,900	67
Torpedo marmorata	150	600	80

These results do not assist in advancing the method by which adrenaline and noradrenaline are formed in the body. However, it is evident that even the pathways through dihydroxyphenylalanine and hydroxytyramine, or through tyramine and *p*-norsynephrine, must be considered doubtful.

FORTHCOMING EVENTS

*(Meeting marked with an asterisk * is open to the public)*

Monday, September 14

Royal Aeronautical Society (at the Royal Institution, 21 Albemarle Street, London, W.1), at 6 p.m.—Prof. N. J. Hoff (New York): "Structures" (Forty-first Wilbur Wright Memorial Lecture).

Monday, September 14—Friday, September 18

Institution of Naval Architects (at the Kurhaus, Scheveningen, Holland)—Autumn Meeting.

Tuesday, September 15—Thursday, September 17

Royal Aeronautical Society (at Friends House, Euston Road, London, W.C.1).—Fourth Anglo-American Aeronautical Conference.

Seventh World Cocoa Conference (at Grosvenor House, Park Lane, London, W.1).

Wednesday, September 16

Physical Society, Colour Group (in the Physics Department, Imperial College, Imperial Institute Road, South Kensington, London, S.W.7), at 3.30 p.m.—Mr. Ralph M. Evans (U.S.A.). "Some Aspects of White, Grey and Black".

Thursday, September 17—Saturday, September 19

Royal Geographical Society (joint meeting with the Institute of Biology, at 1 Kensington Gore, London, S.W.7), at 10 a.m. each day.—Symposium on "The Biology and Productivity of the Sea".

Society for Water Treatment and Examination (at Manchester).—Autumn Meeting.

Friday, September 18

Biochemical Society (in the Department of Biochemistry, The School of Medicine, Leeds), at 11 a.m.—Scientific Papers.

Friday, September 18—Sunday, September 27

International Scientific Film Association (in the Recital Room, Royal Festival Hall, and the National Film Theatre, London, S.E.1).—Seventh Annual Congress.

Saturday, September 19

Amateur Entomologists' Society (at Buckingham Gate Central Schools, Wilfred Street, London, S.W.1), 2–5.30 p.m.—Exhibition*.

Saturday, September 19—Friday, September 25

Royal Photographic Society (at 16 Princes Gate, London, S.W.7).—Centenary International Conference on "The Science and Applications of Photography".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Professor of Social Science at the Victoria University College, Wellington, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (September 17).

Head (honours graduate in chemistry, physics or metallurgy, with teaching, industrial and/or research experience and with corporate membership of a professional institution and preferably with experience of administration in a senior technical college) of the Department of Pure and Applied Science, Enfield Technical College—The Chief Education Officer (F/OW/2), 10 Great George Street, Westminster, London, S.W.1 (September 19).

Plant Physiologist (with good honours degree in botany or agricultural botany) at the Unit of Plant Nutrition, Long Ashton, Bristol, to work on the effects of mineral nutrients on the metabolism of crop plants grown in controlled environments—The Secretary, Agricultural Research Council, 15 Regent Street, London, S.W.1 (September 21).

Senior Lecturer or Lecturer in Physics and a Senior Lecturer or Lecturer in Botany at the Nigerian College of Arts, Science and Technology—The Secretary, Advisory Committee on Colonial Colleges, 15 Victoria Street, London, S.W.1 (September 21).

Engineering Assistant, Senior Scientific Officer grade (corporate member of the I.C.E., I.Mech.E. or I.E.E., preferably with university degree, and with at least three years experience in engineering research or development, education or administration), in the Science Department—The Director, Personnel Department, British Council, 65 Davies Street, London, W.1, quoting "Engineering" (September 25).

Physicist (with first- or second-class honours degree) as Hospital Physicist—The Secretary, Liverpool Radium Institute Management Committee, 1 Myrtle Street, Liverpool 7 (September 26).

Principal (with honours degree in engineering or equivalent qualification) for the Kingston Technical School, Jamaica—Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting CDE.114/32/01 (September 26).

Scientists (with first- or second-class honours degree in physics, engineering or mathematics or equivalent qualification, and several years research experience) in the Field Investigations Group—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, quoting TT/683 (September 26).

Assistant Keeper in Zoology (with good honours degree in zoology or equivalent qualification) in the Manchester Museum—The Registrar, The University, Manchester 13 (October 3).

Engineers (3) (with first- or second-class honours degree in civil or mechanical engineering) in the Department of Scientific and Industrial Research, Forest Products Research Laboratory, Princes Risborough, for investigations on timber strength, wood sawing and machining—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting U.99/53A (October 3).

Senior Scientific Officer (with first- or second-class honours degree in chemistry or equivalent qualification, and preferably with knowledge of physical methods applicable to inorganic analysis) to take part in a special investigation needing a sound knowledge of mineral chemistry and general experience of mineral analysis (Ref. No. F.434/53 A); Scientific Officer (with first- or second-class honours degree in chemistry or equivalent qualification, and with sound knowledge of mineral chemistry and experience of mineral analysis) to undertake analysis and examination of minerals and their products, rocks and fuels, and to assist in development of suitable methods (Ref. No. F.435/53A); Assistant Experimental Officer (with G.C.E. with scientific subjects at advanced level, and preferably with experience of applied inorganic analysis) for duties in connexion with mineral analysis and investigations (Ref. 436/53A), at the Directorate of Colonial Geological Surveys—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting appropriate Ref. No. (October 3).

Principal for the College of Technology, Bristol—Chief Education Officer, Council House, College Green, Bristol 1 (October 14).

Lecturer in Biochemistry (preferably with interests in the field of protein chemistry)—The Registrar, The University of Adelaide, Adelaide, South Australia (October 31).

Assistant Experimental Officer (with H.S.C. science or equivalent qualification, and with experience in research and development work in spectro-chemical analysis) at the Atomic Energy Research Establishment, Harwell—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting F.438/53A.

Assistant Lecturer, Grade B (with honours degree in chemistry) in Chemistry—The Registrar, College of Technology and Commerce, The Newarke, Leicester.

Assistant Superintendent, Senior Scientific Officer grade (with thorough knowledge of the use and testing of textile and related material used on railways), in the Textiles Division, Research Department, Derby—The Director of Research, The Railway Executive, 222 Marylebone Road, London, N.W.1.

Chemist (with good honours degree in chemistry and with ability to study agronomic problems and knowledge of soil chemistry and physics, and the layout and analysis of modern fertilizer trials) at the Sugarcane Research Station, Mauritius—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting 27106/37.

Junior Fellow (engineering graduate, and with an interest in experimental aerodynamics) in Aeronautical Engineering, for work mainly on the design of low speed and supersonic wind tunnels—The Registrar, The University, Bristol 8.

Lecturer (with experience and special interest in micro and semi-micro analysis, and with industrial or research experience) in Inorganic Chemistry, and an Assistant, Grade B (with good honours degree in chemistry) in Organic Chemistry—The Clerk to the Governors, South-East Essex Technical College, Longbridge Road, Dagenham, Essex.

Physicist (with first- or second-class honours degree in science and preferably with five years experience as a hospital physicist) in the Medical Department, Hong Kong—The Director of Recruitment (Colonial Service), Colonial Office, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting CDE.117/51/013.

Scientific Officer, Grade 2 (with good honours degree in physics or engineering) at the Mechanical Engineering Research Organization, East Kilbride, to work on problems of friction and adhesion—Director of Research, The Railway Executive, 222 Marylebone Road, London, N.W.1.

Senior Hydrologist (with honours degree in an applied science, preferably civil engineering, and with experience in all aspects of river gauging, rainfall, run-off studies, evaporation, study of ground water, and the determination of the water resources of catchment areas) in the Hydrology Section, Public Works Department, Kenya—Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting CDE.112/7/012.

Senior Lecturer (with good honours degree and with industrial and research experience) in the Heat Engines Section of the Department of Civil and Mechanical Engineering—The Secretary, The Royal Technical College, Glasgow.

Senior Lecturer (with degree in agricultural, veterinary or pure science) in physiology of the sheep in the Department of Sheep Husbandry and Wool, Massey Agricultural College—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1; or The Registrar, Massey Agricultural College, Palmerston North, New Zealand.

Senior Scientific Officer (with first- or second-class honours degree in chemistry or metallurgy, and with at least three years post-graduate research experience in electrodeposition or allied fields) to take charge of all research on electrodeposition of metals, including improvements of chromium deposits, devising methods for alloy deposits, and physical examination of deposits (Ref. F.432/53A); Experimental Officers (*a*) Chemist (with H.S.C. science or equivalent qualification) for research on electrodeposition of improved metals and alloys, adhesion of electrodeposits to 'difficult' substrates, electrochemical and chemical polishing, and (*b*) Metallurgist (with H.S.C. science or equivalent qualification) to participate in gunfiring trials and to undertake detailed inspection, including metallographic examination of fired barrels (Ref. F.433/53A), at a Ministry of Supply Research Establishment in South-East London—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting appropriate Ref. No.

NATIONAL PARKS IN BRITAIN

THE debate on national parks which took place in the House of Lords on May 19 had at least the merit of re-directing attention to the weakness in organization of the National Parks Commission, which the third report of the Commission had again emphasized. Little exception could be taken to the trend of Lord Mancroft's reply on behalf of the Government: he was manifestly anxious that the whole project should succeed, though the sincerity of his concern over the education of the public in 'country behaviour' could well be attested by more reasonable financial support for the Commissioners in their publicity. Lord Silkin, however, whose motion initiated the debate, was a little disingenuous in his disappointment that the idea of national parks in Great Britain had not been received by the public as well as had been hoped. He might with more honesty have recognized that some measure of responsibility lay with his own failure to make the National Parks Commission a stronger body with executive functions of its own and reasonable financial resources, so that its activities were not limited by the meagre resources of such counties as Westmorland or Merioneth. Indeed, when he deplored the absence of wardens to check the litter left at some beautiful places of popular resort, he might well have remembered his own responsibility for the restraint on the appointment of wardens by park boards to 'access land', that is to say, wild, uncultivated land, to which public access has been given by a specific agreement or order.

While, however, Lord Mancroft can argue with reason that the Commission is wise to feel its way gently in the first years of its life, the pace of change in the countryside is accelerating and is already threatening the loveliness of even the more remote moorland, downland, and coastal districts of Britain. Moreover, the growing threat comes in the main from government departments, public authorities and large industrial undertakings, which the National Parks Commission has no effective means of checking or controlling. Further, its allies in the defence of amenity like the National Trust, the Council for the Preservation of Rural England and others are dependent on voluntary public support and have already liabilities which exceed their limited income. The Council for the Preservation of Rural England had an income of only £5,843 in 1952–53 and an expenditure of £6,370*; its Sheffield and Peak District Branch† had an income of £1,630 and an expenditure of £1,459. Like the National Trust, the Council and its branches urgently need a considerable increase in membership if they are to continue to carry on their work effectively even on the present scale.

---

* Council for the Preservation of Rural England. Twenty-seventh Annual Report, 1952–53. Pp. 60+4 plates. (London: Council for the Preservation of Rural England, 1953.)

† Council for the Preservation of Rural England, Sheffield and Peak District Branch. Annual Report 1953. Pp. 28. (Sheffield: Mrs. G. Haythornthwaite, Hon. Secretary, Endcliffe Vale House, 1953.)

Awareness of all this lies at the root of the unresolved conflict between amenity and development or other claims on the use of the land; nor is it obvious how to check undesirable developments without hindering legitimate change. It is for this reason that Lord Mancroft's claim that the number of parks already designated represents a considerable achievement would be received with some scepticism, even had the safeguards of independent park planning boards been rigorously applied. It is idle to pretend that parks exist where, in fact, they are little more than paper plans. Not merely the House of Lords debate and the reports that have already come from the National Parks Commission, but also the first report of the Peak Planning Board and the annual reports for 1952–53 of the Council for the Preservation of Rural England and of its Sheffield and District Branch fully confirm the desirability of an early overhaul of the powers of the National Parks Commission; only in this way can some sense of reality be brought into the whole question of planning before the balance has been irretrievably destroyed by unilateral action and decisions taken by interested parties.

Development, complains the Peak Planning Board, has caused considerable injury to some of the finest scenery in this, the first of the national parks. Too many buildings, and unsuitable material for them, are permitted. Widespread destruction of amenities and of agricultural values is feared from clay working, and in spite of emphatic objections from the Peak Board, the National Coal Board was allowed to prospect for open-cast coal, although open-cast working within the Park was successfully opposed by the Peak Board. Details recur in the report of the Sheffield and Peak District Branch of the Council for the Preservation of Rural England, which tells also of efforts to curb the growing threats from lime quarrying and cement works, and the danger to the grandest scenery of the Derwent, including the Cutgate Pass from water schemes; to Sheffield's Green Belt from housing developments; and to Bakewell's river pastures from a proposal to revive an abandoned scheme for a by-pass road.

Two points are worth noting in this connexion: first, the burden which the public inquiries place on the amenity societies. The Sheffield and Peak District Branch, for example, had to face seven public inquiries within six weeks, one of which lasted four days, and the annual report rightly directs attention to the unequal position of the voluntary defenders of the scenic heritage of Great Britain opposing powerful interests, who not infrequently have been also the judges in their own cause. Secondly, this difficulty has arisen in the earliest of the national parks, where the vigour and effectiveness of the Joint Planning Board have already won it the warm support of some of those who most strongly opposed its formation. Similar dangers, however, threaten areas like Snowdonia, Dartmoor and the Lake District, where the system of management is far less satisfactory, and hydro-electric schemes or claims for training areas have weaker opposition to face.

Few can now entertain the idea that 'designation' as a national park or Nature reserve confers an absolute safeguard against loss of natural beauty. So far the attempts made to balance practical considerations against the preservation of amenity have led to such confusion and frustration that the impression might well be gained that designation increases the risk of destruction of natural beauty. To say the least—and without challenging the condition that inclusion of land in a park effects no change in ownership or right of public access, or the need for proper safeguards for the interests of agriculture, forestry, transport, industry and for other public needs in the areas concerned—it may well be held that in practice the claims of amenity have been put so low that the value of declaring an area a national park, under present conditions, is extremely dubious.

How far the damage already done is irreparable may be a matter of opinion; but clearly attrition, particularly in those areas like Dartmoor where the park is entirely under local authority control and the first consideration appears to be the avoidance of any charge to local ratepayers, is proceeding at a rate which will not brook delay. To safeguard the Norfolk Broads, for example, demands early action and cannot be postponed indefinitely as Lord Mancroft seemed to imply. Lord Chorley apart, there was little sense of urgency apparent in the House of Lords debate, and it is evident that an upsurge of public opinion is required to compel the Government to give adequate attention and resources to the whole question.

There can be little doubt that the presence of the National Parks Act and Access to the Countryside Act on the Statute Book has given a false sense of security in this matter to the general public, and the most strenuous efforts of the Commission itself and of the amenity societies will be required to secure appropriate action before Britain's scenic heritage, to say nothing of its flora and fauna, are irretrievably damaged. In these circumstances it is the more unfortunate that the membership of bodies like the National Trust and the Council for the Preservation of Rural England is comparatively so small and shows such slight signs of increase. A significant rally to the support of such bodies and a marked increase in their membership could give clear warning to the Government that the defence of amenity is not merely a concern of a tiny minority, but one in which a large and active body of citizens is deeply interested.

Apart from this, such voluntary bodies have an important function to perform in the defence of amenity even if the National Parks Commission is strengthened and the administration of the Parks placed on the basis which was recommended by the Hobhouse report. The annual report of the Council for the Preservation of Rural England shows clearly how much will still remain to be done by voluntary bodies in the way of investigation and negotiation for the purpose of finding practicable and acceptable solutions to the real problems which arise when natural beauty is challenged by some other public need. It is not merely that bodies like this Council have a wider orbit than any particular park planning authority, however constituted, or even than the National Parks Commission itself. The defence of amenity is properly the concern of every good citizen, and it is fitting that the defence should be rooted deeply in local knowledge. Nor can the park boards or the Ministry of Housing and Local Government be expected to carry out the unspectacular work which can do so much to reconcile in part conflicting claims, or to mitigate the effect on the beauty of the countryside of an adverse decision by authority.

The work of the Council for the Preservation of Rural England in such matters as refuse dumps in rural areas, the control of camping and caravan sites, of advertising and the preservation of buildings indicates how much such a body can contribute in the way of pooling advice and experience, and securing the reconsideration of projects advanced in ignorance of possible alternatives which would cause less damage to amenity. Such work is arduous and continuous; but the present report gives several instances of its success. More could be done if the financial resources of either the Council or the National Parks Commission were greater; but even as it is, the work of the Council in such fields attests the existence of the spirit of co-operation on which the Minister of Housing and Local Government has rightly laid much stress. Such questions as road services and footpaths in the park areas provide other evidence of the possibility that a stimulus may be given which could bring fresh vitality to the whole task of local government in such areas. The success of the scheme for mapping footpaths and bridleways throughout Great Britain depends on the interest and co-operation of country lovers and users, and here also the Council for the Preservation of Rural England has been active, examining, *inter alia*, the possibility of an alternative to the proposed Thames Riverside Walk which for economic reasons the National Parks Commission had abandoned last autumn as a long-distance route.

The Council's annual report for 1952–53 gives a clear picture of some of the possibilities in all these fields, provided that it receives the backing it deserves. Already it has done, and is doing, much exploratory work that could help the National Parks Commission to deal wisely and effectively with the problems that a properly constituted park authority will have to solve at the regional and at the national levels. The reports here discussed show clearly the dangers involved in the present situation, and the urgent need for disturbing the complacency which marked the House of Lords debates and has characterized official attitude to national parks hitherto. An unmistakable rally of public support to the Council and to the other societies for the protection of amenity would not only enable them to extend their work and to do it more effectively: the increase in membership might well help the Minister to change his whole attitude to national parks, and convince the Government that here is a national interest to which something more than lip service must be given.

ROLE OF NITROGEN IN PLANTS

Nitrogen in the Life of Plants

By Dr. Dimitrii Prianischnikov. Translated by S. A. Wilde. (U.S.S.R.: Academy of Science; Madison, Wis.: Kramer Business, Inc.)

DIMITRII PRIANISCHNIKOV, who died in 1948 at the age of eighty-three, was probably the last of the great pioneers in the application of chemistry to problems of fundamental agricultural importance. For more than fifty years he had been at work at the Timiriazev College of Agriculture near Moscow and, trained as he was under Timiriazev himself, he was a direct link with Boussingault, whom he met, and with Liebig. When he started research under Ernst Schulze at Zurich in 1892 on the role of nitrogen in the life of plants the number of simple nitrogenous substances that had been isolated from plant material was not very large, and ideas about protein structure and metabolism were rudimentary. The application of nitrogenous dressings in agronomy was, of course, already well known, but the great advance that followed the introduction of cheap synthetic products for this purpose was to come later. The book under review, written when he was nearly eighty, is cast largely in the form of a personal narrative, and in it he portrays the history of the subject as it unfolded during his lifetime and incidentally shows us the important part that he himself played in its development. It is a 'period piece' to be treasured as well as read with profit by those who would follow in his footsteps.

In the first chapter he discusses the early history of the nitrogen problem in plants from the time of Glauber, and his interpretation of the literature leads him to conclude that Boussingault has a greater right even than Liebig to be regarded as the founder of modern agrochemistry, in that he was a more exact experimentalist than Davy and had views on the nitrogen nutrition in plants which were well ahead of those of Liebig. In the next chapter he discusses the early work on the forms of nitrogen available to plants, and gives a brief summary of the controversies that arose between Boussingault, Liebig and others as to the role of ammonia and nitrate in plant nutrition and on the question of nitrification in the soil. He again directs attention to the more exact experimental techniques employed by Boussingault.

The third chapter, dealing with the role of ammonia and amides in plant metabolism, is, perhaps, the most valuable one in the book because, *inter alia*, he gives us for the first time and fifty years after the event his own version of the controversy that he had with his old teacher Schulze on the chemical mechanisms leading to the production of asparagine in germinating seedlings. For more than twenty years before Prianischnikov went to work with him, Schulze had been laboriously isolating and estimating the asparagine and amino-acids present in seedling saps, and had obtained much evidence that was in direct contradiction to the concept, widely held by contemporary plant physiologists under the masterful leadership of Pfeffer at Leipzig, that the amide was a primary product of protein decomposition. In his opinion the amino-acids were the primary products and asparagine was derived from these by a secondary process about which he hesitated to express dogmatic views.

Prianischnikov, who started a series of comprehensive seedling analyses in Schulze's laboratory in 1892, and continued them on his return to Moscow, put forward the suggestion, based on reasonable but indirect evidence, that the essential intermediate in this secondary process was ammonia. Schulze, who had himself adumbrated the same idea in 1888, but had been unwilling to adopt it for lack of direct chemical evidence, was unconvinced, and was to remain so until Prianischnikov and his pupils produced, in the years between 1905 and 1912, what was probably valid, though still indirect, evidence that some oxidative mechanism was concerned. In his account of the development of the subject during the twenty years 1892–1912 the reviewer is of the opinion that Prianischnikov has perhaps been just a little ungracious to his old teacher. In his earlier years Schulze had been strongly influenced by the work and philosophical approach of the first great master in protein chemistry, Ritthausen, whose book "Die Eiweisskörper der Getreidarten, Hulsenfrüchte und Ölsamen", published in 1872, he regarded as a landmark. He was convinced that the interpretation of plant metabolism must be based on sound chemical observation and was thus led to spend most of his life combating what was to him the evil influence of the speculation that was rife at that period in the literature of plant physiology.

Prianischnikov, as a younger man, must have found Schulze's views dull and rather unimaginative, just as the casual reader of Schulze's numerous papers would do to-day. In the event his interpretation of the role of ammonia in asparagine production has been shown to be correct; but some of the evidence that he advances in support of it in his book (pp. 18, 19) is culled from Schulze's earlier work, and this is not brought out quite as clearly as it might have been. The controversy, of course, is of no more than historical interest to-day but it should never be forgotten, for these early views on the role of ammonia in amino-acid metabolism antedated by several years the more definitive work of Knoop on oxidative deamination in the animal organism. Such criticism, nevertheless, need not lessen our appreciation of Prianischnikov's own contribution, and his thesis that ammonia was the alpha and omega of protein synthesis and degradation in plants undoubtedly helped to clarify what was then a rather confused field of study. In this the influence of Boussingault, who had put forward a similar suggestion about urea in animal protein metabolism, is apparent.

In 1912 Prianischnikov abandoned work in the metabolism of organic nitrogenous compounds and was to devote the rest of his long life to investigations on ammonia and nitrate nutrition in plants, which he realized might yield results of much greater economic importance, especially to a country where agriculture was as backward as it was until recently in Russia. Much of the work that was carried out under his guidance at the Timiriazev College has been inaccessible to those who are unable to read Russian, though the outlines of it have been known to us through the summaries that he published from time to time in German journals. In the last four chapters of his book the whole subject is now treated on a historical basis and his own work is presented in expanded form. Once again we can be grateful for a long memory and his penetrating assessment of the value of much of the early literature. His own researches will have a lasting effect on agronomic practice and show that he belonged to the ranks of the world's great scientists. There can be no doubt that the contributions which he made to the economic development of his country were profound, and that the honours which came to him in his later years were well deserved.

It is an illuminating reflexion of conditions in the publishing world to-day that the English translation of this unique book should be produced in typewritten form instead of normal print. This complaint nevertheless does not lessen our gratitude to Prof. Wilde and his colleagues for having made the translation available to us. A. C. CHIBNALL

PHYSICS OF THE IONOSPHERE

Die Ionosphäre

Ihre Bedeutung fur Geophysik und Radioverkehr. Von Dr. Karl Rawer. Pp. 189+10 plates. (Groningen: P. Noordhoff N.V., 1952.) Paper, 12.50 florins (28s. 6d.); or cloth, 14.50 florins (32s. 6d.).

THE practical importance of the ionosphere rests on the use which the radio engineer must, perforce, make of it if he is to maintain a modern world-wide communication network. Although the continually changing characteristics of the different layers may be a constant source of anxiety to the engineer, familiarity with similar changes in the past and the use of empirical methods allow him to extrapolate current behaviour into the future with sufficient accuracy for his needs without having to study the underlying physics.

On the other hand, the changes which harass the engineer are grist to the mill of the physicist whose aim is to explain the behaviour of the ionosphere in terms of an atmosphere irradiated by solar ionizing radiation in the presence of the earth's magnetic field.

Books on the ionosphere are rare, probably because the number of potential readers is limited even when both physicists and engineers are included. Small though this number may be, a treatment of the subject, if it is to be successful, must be written either for the physicist or the engineer since their interests and points of view are essentially different. Dr. K. Rawer's monograph is intended primarily for the physicist who wishes to make a rapid survey of ionospheric physics and of the important problems of finding the upper and lower limiting frequencies for the propagation of radio waves through the ionosphere at oblique incidence. In a book of this size, detailed discussion of the wide range of subjects covered is not possible; but space has been found, in most cases, not only for a brief review of the background but also for an indication of more recent developments.

Dr. Rawer would, no doubt, agree with Samuel Johnson's remark that "a man will turn over half a library to make one book". Nevertheless, he has not been indiscriminate in quoting references, particularly to earlier investigations, merely for the sake of completeness; about half of the two hundred and fifty sources quoted refer to work published during the past eight years, and the inquisitive reader who wishes to examine in more detail a particular problem which interests him will find ample guidance for further study. The quality of the typography and make-up of the volume conform to the high standard expected in books published in the Netherlands.

C. M. MINNIS

PHYSICS AND PHYSIOLOGY OF NERVOUS ACTIVITY

The Neurophysiological Basis of Mind

The Principles of Neurophysiology. By Prof. John Carew Eccles. (Being the Waynflete Lectures delivered in the College of St. Mary Magdalen, Oxford, in Hilary Term 1952.) Pp. xi+314. (Oxford: Clarendon Press; London: Oxford University Press, 1953.) 25*s*. net.

THIS book is the outcome of the Waynflete Lectures for 1952, a series of lectures the fame of which in the University of Oxford grew so fast that they had to be moved three times to a larger lecture theatre. The audience was swollen by philosophers and theologians who were spurred on to endure a close-knit exposition of the physics and physiology of nervous activity by the hopes engendered by the title. In the last Lecture, alas, their hopes were foiled. The crock of gold seems at present to be but rainbow gold after all.

Title apart, this is a very good book. It is an attempt to give a complete account of the processes which occur at the synapse—the junction between one cell and another. This has been the main object of the author's work for at least twenty-five years. Starting with myographic work on the flexor reflex with Sherrington, Eccles has pursued synaptic activity in the sympathetic ganglia, has studied the simpler system in the nerve muscle junction and has returned to the spinal motoneurone, continuing to attack it with better methods and better micro-electrodes, until he has succeeded in introducing an electrode into the cell-body itself. He has recorded the electrical signs of excitation and inhibition at the cell membrane and has interpreted them in terms of two chemical processes which result in the breakdown or the stabilization of the cell membrane. Although there are those who do not accept his interpretation, no other interpretation is as yet so well buttressed.

There are many properties of the membrane of the cell-body which cannot be directly measured. The book therefore begins with an account of the recent work on nerve axons chiefly from Cambridge, and of the processes at the nerve-muscle junction chiefly studied by Katz and his colleagues. These are used to fill in gaps in our understanding of synaptic processes.

The author's more recent work on the prolonged effects of repetitive stimulation is used to bridge the gap between the long-known evanescent effects of 'facilitation' in simple reflexes and the almost permanent changes affected by 'learning'. His emphasis on the plasticity of the nervous system is new and most useful. He raises, but does not pursue, the problem of the differences between the effects of natural stimuli which reach the cord from the afferent endings in muscle and the synchronous volleys which can be set up in the same fibres by artificial electrical stimulation. The artificial stimulus gives rise to post-tetanic potentiation, the natural one does not.

In the later part of the book, Eccles uses the present knowledge of the synapse to illuminate and endow with life our knowledge of the cerebral cortex. He discusses at some length the work of Delisle Burns on isolated unanæsthetized slabs of cerebral cortex, and interprets his results in terms of the probable behaviour of networks of nerve cells arranged in a simple lattice structure.

Hebb has remarked that some psychologists regard the brain as having all the fine structure of a bowlful of porridge. It does not seem likely that it is much more profitable to regard the cortex as having the uniformity of structure of a crystal.

It is arguable that at present our greatest need is for some understanding of the smaller units of neuronal organization. At present we have two, the circumscribed 'centre' which experimental observations obstinately fail to support, and the reverberating chain of Cajal, brilliantly used by Lorente de Nó. The full possibilities of the chain are far from being exploited theoretically and the experimental demonstration of its existence is not easy. Forty years ago we had the reciprocally related half-centres of Graham Brown laughed out of court by the Oxford School because such centres could not be precisely localized. So far the simpler brains studied have not been simple enough to teach us much about the organization of neurones.

In his introduction to his chapters on the cortex, Eccles excludes any discussion of the basal ganglia on the rather odd ground that "they are outside the scope of this book". It is clear, however, from the work of Dusser de Barenne, McCullough and Magoun, that the cerebral cortex does what the basal ganglia and mid-brain structures permit it to do. To have some understanding of cortical processes, we need more than a knowledge of the synapse and the probable behaviour of reverberating chains of neurones. This book is synaptology at its best; but synaptology, alas, is not enough.

D. WHITTERIDGE

STABILITY AND CONTROL

The Principles of the Control and Stability of Aircraft

By Prof. W. J. Duncan. (Cambridge Aeronautical Series.) Pp. xvi+384. (Cambridge: At the University Press, 1952.) 40*s*. net.

THIS is the first volume of the new Cambridge Aeronautical Series, edited by Ernest F. Relf, which was originally planned in the College of Aeronautics at Cranfield. The author, Prof. W. J. Duncan, now Mechan professor of aeronautics and fluid mechanics in the University of Glasgow, has had a most distinguished career at the National Physical Laboratory and afterwards as professor of aerodynamics in University College, Hull, and then in the College of Aeronautics, Cranfield. He is undoubtedly one of the greatest living authorities on problems of stability and control of aircraft and of aerodynamic vibrations, and with Dr. R. A. Frazer he made the first systematic investigation of the problem of flutter, on which he is one of the outstanding experts. Through his work on the Aeronautical Research Council and its committees and sub-committees, he has been in continuous contact with the new discoveries and developments in this important branch of aeronautics, and it is difficult to think of anyone better qualified than Prof. Duncan to write an authoritative exposition of the principles of the control and stability of aircraft.

The subject itself is a most important and a complex branch of aeronautics. Unfortunately it has hitherto been almost inaccessible to students because most of the recent developments are still available only in original reports and papers and have scarcely begun to find their way into text-books.

This applies especially to the important recent developments made during and after the Second World War. The book gives a lucid and systematic exposition of a branch of aerodynamics which has hitherto been available to students almost solely through oral tradition.

The wide range of subjects covered by the author can be gathered from the fact that it includes discussions of problems of aero-elasticity (including the effects of flexibility of wing, fuselage and tail-plane), the effects of compressibility, automatic stabilization, a general survey of our knowledge of flaps, and the phenomena of stalling and spinning of aircraft. The last two topics are discussed in two chapters contributed by Prof. A. D. Young, of the College of Aeronautics, Cranfield.

The general plan of the treatise is to proceed from an elementary introduction of the mechanics of flight to the equations of motion of the rigid aircraft and to the solution of the dynamical equations and the investigation of stability. This is followed by a separate study of longitudinal-symmetric motion and lateral-antisymmetric motion. A special chapter is devoted to measurement of aerodynamic derivatives, and two other chapters to flap controls and controls for rolling, pitching and yaw. Other topics discussed in the book are static stability and manœuvrability.

There can be no doubt that this text-book is destined to become the classical reference for all problems of stability and control. Its clarity, simplicity, systematic arrangement and comprehensiveness make it an outstanding achievement of aerodynamic exposition.

ADVANCES IN CATALYSIS

Advances in Catalysis and related Subjects
Edited by W. G. Frankenburg, V. I. Komarewsky and E. K. Rideal. Vol. 3. Pp. xi+360. 7.80 dollars. Vol. 4. Pp. xi+457. 9.50 dollars. (New York: Academic Press, Inc., 1951 and 1952.)

THE task of providing an authoritative account of the present state of knowledge in the field of catalytic chemistry is a formidable one; but the importance of the theory, practice and industrial aspects of the subject must be held to merit the publication of the present series of volumes.

In the development of any theory of catalysis the number of factors affecting catalytic phenomena which have to be taken into account are many and varied and must include, for example, the chemical nature of solid catalysts and the structure, even the fine or electronic structure, of their surfaces, chemical and physical adsorption and desorption processes, the effects of catalyst poisons, ageing of surfaces, the formation of intermediates and the properties and behaviour of the products towards the catalyst surface. These are but a few of the variables which emphasize the complex nature of the sequence of processes occurring in a catalytic reaction.

These two volumes present articles by well-known workers on different aspects of catalysis, and the editors decided no attempt should be made to link these articles by anything approaching a universal theory. This was a wise decision, not only because of the absence, at present, of a universal theory of catalysis, but also, as the editors point out, since to do otherwise might have had the effect of hampering free expression of opinion by the authors. The result is that in both these volumes we have a stimulating blend of the theoretical aspects and the practical applications of many facets of surface catalysis.

Volume 3 contains eight articles of fascinating variety. It is pleasing to find that the first article gives a lucid account of Balandin's contributions to the consideration of the geometry of surfaces and the correlation of this with catalytic activity. There follows a discussion of the application of magnetic methods to the study of catalyst structure. Here, the experimental methods are clearly described and the resulting information critically examined.

The interest of the general reader is further stimulated by the abrupt change from the subject-matter of these two articles to that of the following one which deals with the catalytic oxidation of acetylene in air. This is an intensely practical problem and its importance lies in the application of such catalytic methods to the removal of the very small amounts of acetylene in atmospheric air in order to eliminate the explosion hazard in the manufacture of oxygen by distillation of liquid air.

The poisoning of metallic catalysts has always been a question of interest from the theoretical and the practical points of view, and a major work on surface chemistry would not be complete without consideration of this topic. The discussion, by Prof. Maxted, gives a good picture of our present state of knowledge; it is stimulating to consider this article in conjunction with a later one on nickel sulphide catalysts.

Some features of the catalytic cracking of hydrocarbons and the chemical characteristics and structure of cracking catalysts are ably dealt with in two chapters, and the volume is completed with a discussion of reaction-rates within the porous structure of solid catalysts.

In Volume 4, further problems in catalytic cracking processes are considered in two articles, one of which is devoted mainly to the sintering properties of catalysts used in these reactions.

Catalytic phenomena in homogeneous media are represented in this volume by authoritative contributions on acid-base catalysis, the free radical mechanism in the reactions of hydrogen peroxide, and the specific reactions of iron in some hæmoproteins.

Two articles on adsorption give, rather briefly, representative pictures of this important feature of catalytic problems. One of these is restricted to a review of recent aspects of the statistical thermodynamical theory of physical adsorption, while the other is concerned with the role of surface heterogeneity in adsorption.

A historical review of the catalytic synthesis of hydrocarbons from carbon monoxide and hydrogen provides a useful summary of the main steps in the development of this process. Much of the article is devoted to the work of Franz Fischer and his co-workers; but developments in other countries are also summarized, and there is a section on some solved and unsolved problems of hydrocarbon synthesis.

These two volumes are in keeping with the standard set by the earlier volumes in this series, and it seems certain that the editors' hope that they will be of very substantial help to both the specialist and the novice in the field of surface catalysis will be realized.

James Bell

SCIENCE AND ETHICS*

By the Most Rev. and Right Hon. CYRIL F. GARBETT, Archbishop of York

Use and Misuse of Science

THE history of civilization shows how man always has to choose between making the right and wrong use of the discoveries of science. This has never been more true than in our own age. In a brief period amazing discoveries have been made and applied to practical purposes. It has become a platitude to say we are living in an age of revolution. Within the life-time of many of us the social and economic life of a great part of the world has been transformed by practical science.

It would be ungrateful not to recognize how immense are the boons which science has given to mankind. It has brought within the reach of multitudes benefits and advantages which only a short time ago were the privilege of the few. It has shown how malnutrition, hunger and disease can be overcome. It has not only lengthened life, but it has also deepened its quality. Fields of knowledge, experience and recreation open in the past only to a few have been thrown open to millions. Through the work of science the ordinary man to-day has been given the opportunity of a longer and fuller life than was ever possible to his grandparents. Most thankfully we must acknowledge all that science both has done and is doing for the welfare of our race.

But the gifts of modern science can be misused as greatly as those of primitive science in the days of Lamech†, and as the gifts are greater, so their misuse can be the more catastrophic. The motor-driven vehicle facilitates business and gives harmless enjoyment to many; but it can strew the road with dead and dying—250,000 casualties in one year in Great Britain alone. The cinema is a means of instruction and recreation opening 'magic casements', but it is often a channel of vulgarity and false values. The wireless can link the world together in a moment of time, but it can also be the instrument of lying propaganda. The aeroplane makes travel rapid and easy, but it can also become a weapon of destruction.

The Dilemma of Science

It is this twofold aspect of the use to which science can be put which has raised in an acute form the question as to how far it is morally justifiable to make and apply discoveries and inventions which can be used for destruction or result in the ultimate impoverishment of man. This, if I understood it rightly, was the dilemma posed by Prof. A. V. Hill in his presidential address to the British Association last year. He summed it up in the question: "If ethical principles deny our right to do evil that good may come, are we justified in doing good when the foreseeable consequence is evil?" He drove home this question by two problems. The first was taken from the development of nuclear physics. This, rightly used, should be of the greatest value to mankind, especially if existing sources of power come to an end. But at present the development of this science is largely concerned with producing weapons, like the atomic and hydrogen bombs, of unprecedented destructive power. Is it right, therefore, to continue research on lines which may lead to fearful destruction, and is it right to keep secret the result of these researches? The other problem arises from the success of science in overcoming disease and lengthening life. Both the birth-rate and the expectation of life have been increased by the removal of the older checks of hunger and disease on the growth of population. But the supplies of world food are not increasing at the same rate. Before long, population will have outstripped the food available to feed it. When this happens the scramble for it will be intensified as the world becomes divided more than ever into 'Haves' and 'Have nots'. War for the means of existence will be inevitable, and in the fight against starvation the land will be exhausted and soil erosion will change fertile plains into dust bowls. Is it right to continue improving world health and reducing mortality if by doing so future famine and disorder become certain? These and other questions are a challenge to thoughtful men. *The Times*, in commenting on this address the next day, said it was a call for a statement of moral principles, and continued, "Theology was once known as the Queen of the Sciences. If science as the servant of humanity is to be sure of its direction, the queen needs to be either re-instated or replaced. . . . The throne is at present vacant".

Integrity and Secrecy

To the questions thus asked, Christian theology must attempt some answer, though often it cannot be clear-cut and decisive. The Christian theologian is in complete agreement with the man of science when he asserts that the fundamental principle of all research work is unbending integrity, and that evidence must be followed to its logical conclusions however disagreeable they may be. The Christian must welcome truth from whatever quarter it comes, for his Lord is the Truth as well as the Way and the Life. A sound Christian theology insists that the love of truth is as important as the practice of truthfulness. It is deeply to be regretted that sometimes Christians have forgotten this and denounced new discoveries, not because they were untrue, but because they feared they would be dangerous and unsettling to faith. The Christian has the right to criticize the validity of any theories. It may be necessary for him to suspend for a time final judgment on them; but he has no right to reject them solely because their consequences may be disconcerting. Neither Church nor State must attempt to destroy the results of scientific inquiry. The Church must not repeat the condemnation of Galileo nor the State the folly of Stalin on the Lysenko controversy on heredity.

The unrelenting search for truth does not, however, carry with it the conclusion that when discovered it must at once be proclaimed to all and sundry. Men of science have always taken pride in the universal nature of their work; in the past they recognized no national or geographical boundaries, and they were able freely to exchange information with fellow workers in different lands. It is therefore repugnant to them when secrecy is imposed upon them. With this position Christianity fully agrees, for as it teaches the Fatherhood of God and the brotherhood of man, we should share unselfishly with others our knowledge and advantages. But Christian theologians have also recognized that there must sometimes be delay or reservation in imparting truth, for there are many who are still incapable of receiving it, and to some it would be like the casting of pearls before swine. Truth must be imparted according to the measure in which men are capable of receiving it and using it rightly. The Christian moralist therefore holds that discoveries and inventions can be justifiably kept secret from those who might use them for evil purposes. A State is within its rights in demanding that secrecy should be observed about inventions made by those whom it has employed when they are intended for its security but might be used by an enemy for its destruction. This secrecy is a temporary expedient due to the evil times in which we live.

---

* Substance of a sermon preached in Liverpool Cathedral on September 6, on the occasion of the meeting of the British Association.

† Genesis, iv, 23, 25.

The Christian Answer

It is over the application of science to human life that moral problems arise most sharply. The Christian approaches them with the conviction that every individual is of value. He is not alone in this conviction. Many who are not Christians hold it equally strongly; but the Christian conviction is founded on the belief that God Who is Love has made man in His image, so that He can love man and man can love God. Man is of value, for he is of divine origin and destined for eternity. It was natural, therefore, that Christ should have branded contempt as one of the gravest of sins, for who are we to treat as fools or worthless those whom God loves? If once the value of the individual is discarded, the way is thrown open to the theories of race superiority which divide mankind into master and slave races. These were carried to their logical extremity by the Nazis in their hideous massacre of all who had Semitic blood, by their enslaving of non-Aryans, and by their liquidation of those who through feebleness of mind or weakness of body were likely to become a burden to the State.

All who believe in the value of the individual are therefore bound to ask of any discovery or invention whether it will heighten life or destroy it. But life to the Christian means far more than physical life, for man has a soul as well as a body, and the physical side of his personality must not be developed at the cost of the spiritual. The Christian, therefore, must always ask whether a new discovery can be so applied as to enrich the whole of man.

Nuclear Warfare

Tested by this standard, all methods of mass destruction, whether by obliteration bombing, by nuclear weapons, by gas, or by bacteriological warfare, are condemned, for they destroy as worthless flies those whom God loves and has made in His own image. Their special wrongfulness lies in the contemptuous and indiscriminate destruction they bring upon masses of men, regardless of whether they are combatants or non-combatants, or of sex or age. The total abolition of war and its causes must be the ultimate goal. To reach it will be a long and difficult journey. But as in the past certain methods of warfare were successfully banned as contrary both to natural and divine law, so in our century it should be possible for the world of nations to discover means by which indiscriminate destruction could be outlawed. No one nation can do this in isolation, for if it threw down its most effective weapons of defence it would only excite attack from its rivals who had remained fully armed. Unilateral action of this nature on the part of a nation might secure for it some physical safety, but at the risk of losing its soul, for if it should come under the totalitarian yoke, its citizens would soon lose all that makes a full life possible, for man has a soul as well as a body, and "what shall it profit a man if he loses his soul?"

The terrible dilemma between refusing to make these weapons and thus endangering the freedom of a people, or making them and then employing them for appalling destruction, can only be solved by international agreement with effective inspection and drastic sanctions for any breach. All men of goodwill should urge that at the earliest practical moment renewed attempts should be made to forbid the making or the use of these weapons of mass destruction. Until such an effective international agreement is reached the world is threatened with destruction.

Population and Hunger

The same principle of the value of the individual demands that everything possible should be done to preserve life. Once a human being has been born he has the right to live, however lowly or even degrading may be the circumstances of his birth or his social environment. The Indian, the Chinese and the African have the same right to food and health as their more fortunate white brethren. Science has shown how crops can be greatly increased by new methods of agriculture, and how disease can be reduced or banished. But it can do comparatively little unless the more prosperous communities are prepared to make sacrifices for the sake of saving the backward peoples from destitution and starvation. Such sacrifices may mean that the more prosperous nations will have to accept for a time a lower standard of living for themselves.

It is only when food is no longer the chief preoccupation in life and the struggle for bare survival is relaxed that man has leisure to concern himself with the quality of life. Only then will it be possible to educate him into a sense of parental responsibility which will prevent him from bringing into the world more children than he can reasonably hope to support. For however great may be the increase in the food supplies of a country, the growth of population will soon again outpace them if parentage is without foresight, and the birth-rate of backward countries continues to multiply. Side by side with the aid that science can give in the production of food and against disease there must be moral and religious education both in the responsibilities and restraint of parenthood. The quality of life is more important than numbers.

Responsibility of Men of Science

The right use of the discoveries of science depends, therefore, not so much on those who made them as on the moral judgments of the community. Man's inventive genius has grown out of all relation to his sense of moral responsibility. He has advanced in technology, but there has been no corresponding advance in his mastery of himself. He has learnt to work in harmony with the laws of Nature more quickly than he has learnt to live in harmony with his fellow men. He has acquired inventions and tools long before he has learnt to use them rightly and wisely. So, like Lamech, he has frequently turned to destructive purposes what should have been used for the common welfare. The use or misuse of science depends on the moral judgments of society, and the Christian believes that right moral judgment depends ultimately upon religious faith in the Sovereignty and Righteousness of God.

Men of science have sometimes claimed that when they have made a discovery they have no more responsibility for the use made of it than any other citizen; but in actual fact this is not the case. For they have an influence over contemporary thought and action which is possessed by no other class of men. They are listened to attentively by those who pay little heed to the ecclesiastic, the philosopher or the poet. Often their casual opinions, even on subjects outside their special field, are given reverent attention. They cannot, therefore, say of any of their discoveries, "take them, and use them as you think fit; this is not our responsibility". They must take an active part in educating their fellow countrymen to use rightly the inventions they have given them. They must make plain the terrifying results which may follow the wrong use of some of them. We should be thankful that so many of our leading men of science recognize this responsibility.

We thank God to-day for the love of truth and the unremitting search for it of so many who have given their lives to science. We thank Him for the rich benefits their discoveries so often have brought to mankind; at the same time we must pray that their inventions may be used for life and not for death, for the development of personality and not for its destruction, for the benefit of all and not in the service of greed or the lust for power, for the glory of God and for the good of the human race.

MEASUREMENT OF THE γ-RADIATION FROM THE HUMAN BODY

By DR. P. R. J. BURCH and PROF. F. W. SPIERS

Department of Medical Physics, University of Leeds

WITH the increasing use of radioactive isotopes in research, industry and medicine, the need has arisen for an apparatus capable of measuring small quantities of these materials which, by accident, may have entered the body. The biological hazards associated with radioactivity are now well known, and it is realized that advance warning by a physical method is necessary if the deposition of radioactive substances in the body is to be kept below agreed maximum permissible levels. The appearance of clinical signs, such as changes in the blood, may occur at too late a stage to be an effective safeguard.

Before the advent of 'artificial' radioactive isotopes, radium, thorium and mesothorium presented the outstanding hazards, and during the past twenty-five years various physical methods for estimating these elements in the body have been attempted. These have included the measurement of radon in the breath and radioactivity excreted in urine and fæces. Apart from the inapplicability of some of these methods, the variability of rate of excretion with time after deposition is often a serious disadvantage, making an estimate of retained radioactivity extremely uncertain.

Direct measurement of the γ-radiation emitted by radioactive elements in the body overcomes many of the ambiguities associated with the sole use of excretion tests. Given a sufficiently sensitive apparatus, it is even possible to detect quite small quantities of energetic β-particle emitters via the bremsstrahlung generated in the body tissues (see Table 2). Early measurements of the γ-ray emission from the body used rather insensitive techniques. Evans[1], with a single Geiger–Müller tube, obtained a lower limit of sensitivity of 100 ng. (1 ng. = 10^{-9} gm.) equivalent radium body content; Hess and McNiff[2], using a single ionization chamber, claimed to be able to detect 15 ng. radium in the body. More recently Sievert[3], using high-pressure ionization chambers, has been able to reduce the standard error to ± 2 ng. with six to eight observations of 2 hr. each made over a period of several months on unexposed individuals, although he points out that there may be systematic errors of the same magnitude. A large high-pressure ionization chamber apparatus has been working for some time in our laboratory[4]. In a single 2-hr. observation the average probable error of measurements on unexposed persons is ± 15 per cent of the normal body radioactivity, equivalent to ± 2 ng. radium. Thus, quite small excesses of radioactivity above the normal can be detected.

The γ-radiation emitted by the body arises principally from the naturally occurring potassium-40 isotope present in body potassium. There may be some districts where the concentration of radium in drinking water leads to body radium burdens giving a γ-ray emission comparable with that from potassium-40[2,3,4]. On the average, the body contains about 0·2 per cent by weight of potassium, and on this account emits some 500 quanta per sec., each of 1·46 MeV. A point source of this strength placed about 40 cm. from an unshielded γ-ray detector in a typical indoor situation would increase the background record by approximately 0·2 per cent. On the other hand, the presence of a human 'source' near the detector will absorb background radiation, and reduce that reaching the detector by at least 2 per cent. It will be seen that the accurate assay of the γ-ray emission from the human body poses problems of considerable difficulty.

On the grounds of stability, reliability and cheapness, high-pressure differential ionization chambers were chosen by us, although it can be shown[4] that an elaborate anti-coincidence arrangement of Geiger–Muller tubes (or, for example, large scintillators with many photomultipliers) should, theoretically, provide a more sensitive performance. In all cases, the degree of resolution of a measurement is mainly a function of the statistical fluctuations of the background.

Only the essential features of the Leeds apparatus will be described here; details of its construction, instrumentation and performance will appear elsewhere. The general layout of the apparatus is illustrated in Fig. 1, and the block diagram of the instrumentation in Fig. 2. The four register ionization chambers are steel cylinders having an effective volume 6·5 ft. long and 11·5 in. in diameter, with ¼-in. walls; the subject lies on a couch beneath them. Water shielding surrounds the entire apparatus and reduces the local γ-radiation background to 10 per cent and the total background to just under 50 per cent of the unshielded intensities. Statistical errors

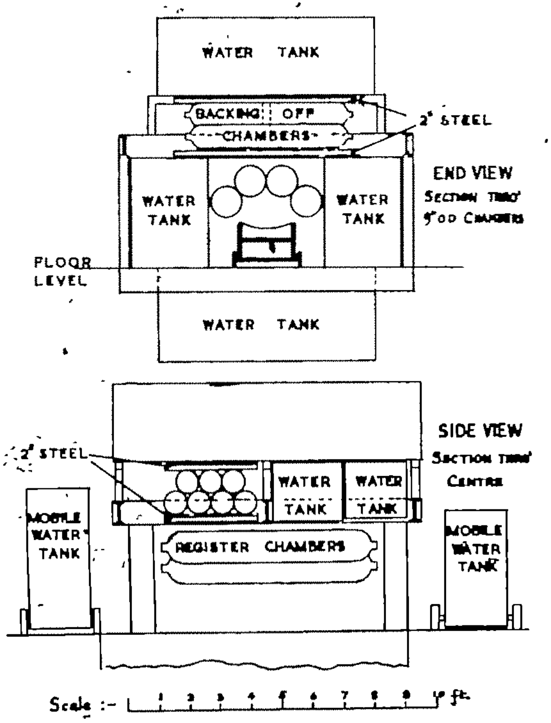

Fig. 1. Body-radiation apparatus. Four recording and seven backing-off chambers. Disposition of shielding at sides and ends of upper chambers is not shown

and the absorption of background radiation by the subject are thereby reduced. Systematic variations in the intensity of cosmic radiation are counteracted by the use of the seven backing-off chambers, and gas pressures are adjusted so that the differential current is unaffected, or only slightly affected by cosmic radiation drifts. Commercial nitrogen has been used and typical working pressures are 13·5 atmospheres in the register chambers and 27 atmospheres in the smaller volume of the backing-off chambers. At these gas pressures, the use of commercial nitrogen (which has a high ionization recombination coefficient) ensures nearly 90 per cent recombination of the ionization along α-tracks arising from traces of radioactive impurities in the chamber walls. Statistical errors from this cause at the low levels of contamination found with these steel chambers then become entirely negligible in comparison with the errors caused by cosmic radiation. The latter produces about 80 per cent of the background ionization and the filtered local γ-radiation nearly all the remaining 20 per cent.

The differential ionization current is amplified by a vibrating-reed electrometer, the output from which is fed into an adapted 'Kent' electro-mechanical recorder, with an automatic averaging device attached to it.

At 4-sec. intervals, the current deflexion on the recorder is automatically converted into pulses which are summed by a scaler. By dividing the integrated deflexion by the number of deflexions recorded, an average current is obtained. Occasionally large bursts of ionization occur in either set of chambers as a result of cosmic ray 'star' events or large showers. The inclusion of these 'anomalous' events could easily lead to erratic averages, so it is arranged that the automatic current-averaging device accepts only those deflexions lying within the range plus or minus twice the standard deviation.

To derive the body radioactivity from the instrument response, corrections must be made for (1) the absorption of background radiation by the subject, and (2) the distribution of the radiation source in the body and the absorption of this internal radiation by the body tissues. The first correction is obtained by measurements with a non-radioactive phantom, a thin sheet-metal container of approximately the shape of the body, filled with distilled water. The ionization produced in the shielded chambers by the normal body radioactivity is still only 0·45 per cent of the residual background, most of which is incident from the vertical hemisphere. A small percentage absorption of cosmic radiation would involve a large correction, and for this reason chambers are disposed only above the subject. As it is, the absorption of background is nearly equivalent and of opposite sign to the emission effect (see Table 1, subject 1). Correction (2) is obtained from the calibration technique. A known quantity (up to 5 μC.) of the 12·5-hr. potassium-42 is administered orally to the subject and the apparatus response determined 4–8 hr. later, during which period the isotope has attained a distribution very similar to that of the normal body potassium. The quantum energies of potassium-42 (1·51 MeV.) and of potassium-40 (1·46 MeV.) are so similar that internal absorption factors are nearly identical for the two radiations. In a previous experiment, the response to a weighed quantity of 'Analar' potassium chloride in a phantom has been compared with the response to a calibrated quantity of potassium-42. From these data the ionization response of the subjects (corrected for background absorption) may be expressed in grams potassium. Although this calibration procedure is only strictly applicable to the potassium content, providing the distribution of any other radioactivity is fairly uniform, a correction may be computed by allowing for differences in attenuation arising between different quantum energies. The total radiation dose received from 5 μC. potassium-42 is 5 mrep., as compared with a typical background dosage-rate of 2·2 mrep. per week.

Measurements have been made on unexposed persons and on others who handle radioactive materials occupationally. Three examples are given in Table 1 to illustrate the component factors in the measurement. Only those occupationally exposed

Table 1

1 Subject	2 Body-weight (kgm.)	3* Response above background	4* Background absorption correction	5* Effective response (3 + 4)	6 Activity as equivalent gm. potassium	7 Expected normal potassium content (gm.)	8 Activity above 'normal'
Medical student, male, unexposed	66	1·2 ± 1·2	+ 6·7	7·9 ± 1·2	150 ± 23	143	7 ± 23 gm. potassium
Radiation worker exposed to cobalt-60 dust	55·7	17·7 ± 1·4	+ 6·3	24·0 ± 1·4	413 ± 24	117	= 296 gm. potassium or 15 nC. cobalt-60†
Former mesothorium worker	70·8	79·6 ± 1·2	+ 6·8	86 4 ± 1·2	1,665 ± 23	149	= 1,516 gm. potassium or 0·12 μC. mesothorium

* Units : 10^{-14} amp., for columns 3, 4 and 5. † 1 nC. = 10^{-9} C. = 37 d.p.s.

have so far shown radioactivity significantly in excess of that expected from body potassium. In a group of unexposed persons (ten male and three female medical students resident locally) the mean potassium content, ascribing all the response to potassium-40, was found to be 0·21 ± 0·01 per cent by weight. It is assumed that the water phantom used for background absorption calibration is free from radioactivity. This result is in agreement with that of Shohl[7], who quotes $0{\cdot}21_2$ per cent, based on chemical determinations, and in harmony with recent measurements of 'exchangeable' potassium (said to be approximately 5 per cent less than total) by Edelman *et al.*[8], who find $0{\cdot}18_2$ per cent (average for thirty-three males) and 0·16 per cent (average for fourteen females). All these estimates conflict with the value 0·35 per cent given by Hawk, Oser and Summerson[9].

Table 2 gives the probable error for a single 2-hr. measurement in terms of the body content of a number of commonly used radioactive elements; the maximum permissible levels suggested by the International Commission on Radiological Protection[10] are included for comparison. For γ-ray emitters a quantity much smaller than the maximum permissible level can be detected; but because β-emitters are assayed via bremsstrahlung, the efficiency of their detection is very much reduced.

Table 2

Isotope	Maximum permissible amount in body	Probable error for 2 hr. observation of body activity
Radium-226	100 ng.	2 ng. (for radium in radioactive equilibrium with decay products) 4 ng. (for 50 per cent excretion of radon in breath)
Thorium-232 Mesothorium-1		2 nC. (or 18 mgm. 'old' thorium)
Cobalt-60	1,000 nC.	1·4 nC.
Iodine-131	300 nC.	10 nC.
Sodium-24	15,000 nC.	1 nC.
Phosphorus-32 (β-emitter)	10 μC.	2 5 μC.
Strontium-89 (β-emitter)	2 μC.	4 μC.
Strontium-90 (β-emitter) (in equilibrium with yttrium-90)	1 μC.	0·5 μC.

The sensitivity of the apparatus would be much improved in a deep underground laboratory where the cosmic radiation component, responsible for the major part of the statistical fluctuations, would be greatly reduced. Sievert has recently assembled an apparatus in such a situation[11].

This work has been supported throughout by the Medical Research Council, including a maintenance grant to one of us (P. R. J. B.). We are indebted to Messrs. Appleby and Taylor of this Department for technical assistance with the construction and assembly of the apparatus.

DETERMINATION OF TOTAL BODY RADIOACTIVITY USING LIQUID SCINTILLATION DETECTORS

By F. REINES, R. L. SCHUCH, C. L. COWAN, Jun., F. B. HARRISON, E. C. ANDERSON and F. N. HAYES

Los Alamos Scientific Laboratory, New Mexico

In the course of developing equipment for other problems[1], we have made some measurements of the total radioactivity content of several humans and a dog, using a technique which may have other applications in biophysics. The equipment used consists of a liquid scintillation detector in the shape of a cylinder 30 in. in diameter and 30 in. high, surrounded by *RCA* type 5819 photomultipliers, forty-five of which were used in these measurements. Cylindrical steel inserts, 14 in. in diameter in one case and 20 in. in diameter in another, 32 in. high and 0·015 in. thick, were placed in the tank, leaving an annular region filled with liquid scintillator (toluene–terphenyl–α-naphthyl phenyl oxazole). A lead shield 5 in. thick was placed around the assembly, leaving only the top of the insert open. The forty-five photomultipliers were connected in parallel and their output fed through a linear amplifier to a ten-channel pulse-height analyser (see Fig. 1).

Energy calibration. In order to determine the pulse-height corresponding to a given γ-ray energy, a cobalt-60 source was placed in several different locations in the insert and the pulse-height spectra were measured. The results for both inserts are shown in Fig. 2. This spectrum was independent of position of source over the central half of the tank

axis. As the source approached the top or bottom, the peak became less well defined. The line represents pulses resulting from the complete Compton degradation of one of the cobalt-60 γ-rays (1·17 and 1·32 MeV. respectively), and the broadening of the high-energy side results from those cases in which both γ-rays are detected simultaneously.

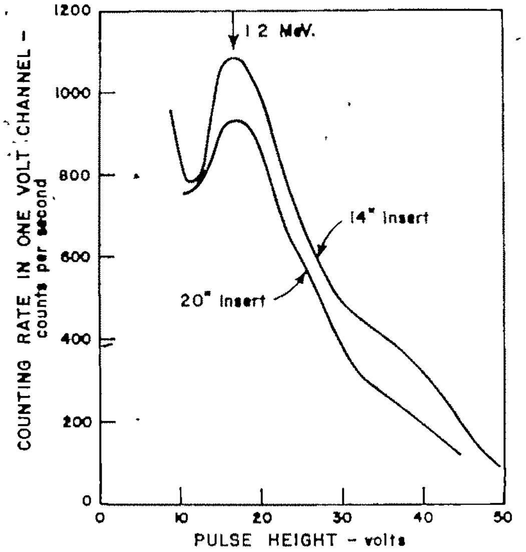

Fig. 2. Counting-rate against pulse height due to a cobalt-60 source placed in the inserts

Data obtained with a dog. A dog of approximately 35 lb. weight was anæsthetized and counted in the small insert. A solution containing 0·1 μC. radium in equilibrium with its decay products was injected in the femoral vein, and (five min. after injection) the dog was again 'counted'. The total counting-rates obtained in the interval 5–35 V., corresponding to 0·3–2·0 MeV., are given in Table 1. The total counting-time for each run was 300 sec.

Table 1. Summary of Results for Experiment on a Dog

Item	Counts per sec.
Background	1,594
Dog before injection, less background	98
0·1 μC. radium solution alone in tank, less background (centrally placed)	1,911
Dog after injection of 0·1 μC. radium, less background	977

From the table it is seen that: (*a*) The counting efficiency per disintegration for the bare source was about 50 per cent. (*b*) The counting-rate from 0·1 μC. of radium in the dog was 879 per sec., giving an overall counting efficiency of about 25 per cent.

Data obtained with humans. The large insert was used for the measurements on humans, who were able by doubling up to be entirely within the insert. The energy gates were the same as in the previous experiment. A background run was made before and after each measurement. The average background counting-rate for twelve runs was 837 ± 6 per sec., and the fluctuations, though greater than statistical, appeared random and consistent with a Gaussian distribution having a standard deviation of 6 sec.$^{-1}$. The fluctuations are presumably due to a slight instability of the discriminator and the rapid rise of background-rate at low energies.

The results of measurements made using various humans are summarized in Table 2. All subjects except 'P. H.' were counted in their normal clothing, and no effort was made to remove radioactive contamination such as might be expected to settle in the hair. The subjects 'W. B.' and 'P. M.' are at present working with radioactive materials; the clothes of 'W. B.' were counted separately, and gave 637 counts per sec. It may be, therefore, that the rather high remaining count was due to external contaminants.

Table 2. Summary of Results for Experiments with Human Beings

Subject	Sex	Weight (lb.)	Counts per sec. above background
'W. L.'	M	130	57
'D. F.'	F	105	80
'W. B.'	M	145	801
'P. M.'	M	160	784
'L. B.'	M	140	42
'H. A.'	M	185	75
'P. H.'	M	140	80
'D. H.'	F	125	57
'G. L.'	F	125	63

Counting efficiency for radium and potassium-40 in humans. The principal natural source of radioactivity in the body is potassium-40. Information on the harmful effects of radioactive isotopes is based principally on persons exposed to radium poisoning. Two experiments were performed to determine the efficiency with which these elements were detected in the counter.

In the first, a mock human form was made by pouring 100 lb. of water into a shaped plastic bag in the insert. The counting-rate was determined before and after the addition of 450 gm. of normal potassium chloride to the water. The net counting-rate from the potassium was 125 sec.$^{-1}$, or 0·52 counts per gm. normal potassium per sec. This number is to be compared with the disintegration-rate[2] of 3·6 γ-rays per gm.-sec., giving an efficiency of 14 per cent. The potassium content of a 70-kgm. person[3] is approximately 150 gm., so the counting-rate expected from potassium alone is about 78 sec.$^{-1}$. It was concluded that most of the activity seen in all subjects except 'W. B.' and 'P. M.' was due to potassium-40.

The efficiency for detecting radium in this counter was determined by counting Dr. Wright Langham ('W. L.') holding a 0·2-μC. standard radium source against his stomach, so that the source was entirely shielded by his body as he sat in the insert. The net counting-rate was 1,133 sec.$^{-1}$, yielding an efficiency of 15 per cent. The statistical fluctuations in the background (± 6 sec.$^{-1}$) correspond to an uncertainty in the total radium of 10^{-9} C. The precision with which it is possible to determine the radium content appears to be limited by the uncertainty in the amount of other radioactive substances present in the body, and by the uncertainty in the degree of elimination of radon, which upsets the radioactive equilibrium of the subsequent daughter products. Most of the gamma-rays detected probably come from radium. It is interesting that, although one of the subjects ('P. H.') has worked for many years with radium, thorium and mesothorium, his radium content appears to be not greater than about 0·01 μC.

Conclusions. In view of the foregoing, it is possible with a counter of this design to determine the total radium content of the body at levels well below the present set tolerance (0·1 μC.), and to make similar determinations for any source giving sufficiently energetic γ-rays. In the absence of the radium group, the potassium content of the body can be measured with good accuracy, and it is quite conceivable that application of these techniques could yield important results in the study of the role of potassium in the metabolic process. These measurements can be made in short times *in vivo* with little inconvenience to the subject.

Since this counter was not designed specifically for the purpose of the present experiment, it should be possible to simplify and improve the system for this type of measurement. For example, the ten-channel analyser could be replaced by a single-channel analyser, or perhaps merely a scaler with a discriminator. Where good energy resolution is not an important factor, it would probably be possible to use many fewer photomultiplier tubes without serious loss of counting-rate. The size of the detector could be increased considerably to accommodate the subjects more comfortably. If smaller animals are to be counted, the counter size and number of tubes could be reduced. Such a counter is being built at this laboratory for studies on dogs.

The background due to cosmic rays was by no means negligible, and would be reduced materially either by additional shielding or by going to sea-level from the altitude of 7,300 ft. at which these experiments were carried out.

It might be possible to reduce background further without seriously impairing the efficiency of detection for the radiation of interest by a more judicious choice of the energy gates.

The superiority of the counter described here over Geiger counters is marked by its high efficiency, energy discrimination for γ-rays, and relatively large volume.

This work was done under the auspices of the United States Atomic Energy Commission. Our thanks are due to Dr. Wright Langham for stimulating conversations and for his generous support.

OBITUARIES

Prof. H. E. Fierz-David

SCIENCE in Switzerland has sustained a great loss in the death on August 25, at Zurich, of Prof. Hans Eduard Fierz-David. Born at Zurich on January 5, 1882, Fierz-David began his education in his native city, eventually specializing in chemistry and prosecuting further studies in London and Munich. In the earlier part of his career he obtained a varied experience of applied chemistry, in particular with the International Nickel Company, also in brewing chemistry, and somewhat later with the firm of J. R. Geigy at Basle. Eventually he developed a special interest in synthetic dyes and the technology of dyes, dyeing processes, and textile fibres. Thus, in 1917 he was appointed to the chair of organic chemical technology, in the Eidgenössische Technische Hochschule, Zurich—a post which he filled with distinction over a long period, until his retirement as emeritus professor. His field of work is reflected in a series of standard publications, including "Grundlegende Operationen der Farbenchemie", "Kunstliche organische Farbstoffe", "Fortschritte der Teerfarben und verwandter Industriezweige", and (with E. Merian) "Abriss der chemischen Technologie der Textilfasern".

A cultured man of wide interests, Fierz-David had an international outlook. He was a good linguist, and he cherished the humanistic aspect of his science. This last feature of his character found effective expression in the elegant historical study of alchemy and chemistry which he published at Basle in 1945 under the title, "Die Entwicklungsgeschichte der Chemie". Significantly, he dedicated this book to his friend, C. G. Jung; for among his varied interests he was a member of the Psychological Club of Zurich. Although an apostle of progress in chemistry and its applications, he deplored the methods of 'mass-production' and the intense specialization to which students are subjected in many modern teaching laboratories. Moreover, he recognized the enormous importance of a human relationship between teachers and students. Looking back to his own student-days, in a letter written a few years ago, he crystallized his feelings for a past order of things into a single sentence: "In this age, one has forgotten how to live".

JOHN READ

Mr. W. N. Croft

WILLIAM NOBLE CROFT, who died on July 10 in his thirty-eighth year, joined the Geological Department of the British Museum (Natural History) as palæobotanist early in 1939, and almost at once set off on a British–Swedish–Norwegian Expedition to Spitsbergen, mainly to investigate Devonian fossils, reaching England again just after the Second World War broke out. Before joining the Royal Engineers, Croft completed a paper on a Lower Devonian flora of the Welsh borderland, though his stratigraphical work on this area is still unpublished. Immediately on leaving the army, he went to the Antarctic for a year as geologist and palæontologist to the Falkland Islands Dependencies Survey; some of the results of this work have recently been published in the Survey's "Scientific Reports". In palæobotany, Croft's main interest centred on Devonian plants; last year he published an account of some Devonian charophytes known as trochiliscs, and he had almost completed a paper on blue-green algæ from the Rhynie chert. He was an accomplished technician, and his room was full of strange gadgets of his own devising, including a sewing-machine converted into a microscope and a bacon-slicer adapted to rock-cutting. The Croft parallel grinding apparatus is in use in many palaeontological laboratories. His colleagues will greatly miss not only his judgment and his insistence on the highest standards in everything he touched, but also his singularly attractive charm of manner.

W. N. Edwards

We regret to announce the following deaths:

Prof. H. M. Hallsworth, O.B.E., first Dale professor of economics in the University of Durham.

Dr. B. Mouat Jones, lately vice-chancellor of the University of Leeds, on September 11, aged seventy.

Mr. A. Marcan, formerly government chemist and chief assayer in Siam, aged sixty-nine.

NEWS and VIEWS

H. Kamerlingh Onnes (1853–1926)

Heike Kamerlingh Onnes, "le gentleman du zéro absolu", was born at Groningen in Holland a century ago, on September 21, 1853. After studying mathematics and physics at the local university, he went to Heidelberg in 1871 to work under R. W. Bunsen and G. R. Kirchhoff. Eight years later he obtained his degree at Groningen with a thesis entitled "New Proofs of the Rotation of the Earth about an Axis". In 1882, at the age of twenty-nine, he was appointed professor of experimental physics and meteorology at Leyden, where he afterwards established the Cryogenic Laboratory which was destined to become famous throughout the world. Under the influence of J. D. van der Waals, Kamerlingh Onnes studied the equations of state and the general thermodynamic properties of liquids and gases. A pioneer of exact physical measurements at low temperatures, his name is associated particularly with the liquefaction of helium in 1908 and with the discovery of the phenomenon of superconductivity. He was a great organizer possessed of infinite patience, and a master of experimental technique, and he trained a staff which included glass-blowers, skilled mechanics and scientific workers from all parts of the world. Kamerlingh Onnes received the Nobel Prize for Physics in 1913 and the Rumford Medal of the Royal Society in 1912. He was elected foreign member of the Royal Society in 1916, honorary fellow of the Chemical Society in 1920, and corresponding member of the Prussian Academy in 1923. During the First World War and during the early post-war years he devoted himself whole-heartedly to relief work in Europe. Modest, genial, cheerful and universally beloved, he died on February 21, 1926.

Earthquake in Western Cyprus

On September 10, at about 6 a.m. local time, an earthquake occurred with epicentre slightly north of Paphos in Cyprus. The shock, which was registered at Edinburgh, was slightly less intense than the most important of the recent earthquakes in the islands in the Ionian Sea, but nevertheless it caused severe damage and casualties. Three villages, Kithasi, Stroumbi and Ayios Nikolaos, were almost completely destroyed and some 135 other villages within a twenty-mile radius from Ktima were seriously damaged. Much damage was done in Paphos, and the electricity supply and other public services were interrupted. About forty persons were killed and more than a hundred severely injured. Some of the casualties were taken to the hospital at Limassol, where the earthquake was also felt. About fifteen hundred people are known to be homeless as a result of the earthquake. Limassol was shaken by a slight earthquake last year; but the greatest of the recent past earthquakes in Cyprus happened on January 20, 1941. According to the International Seismological Summary, produced at Kew, the epicentre was at lat. 35·2° N., long. 33·6° E., which is just north-east of Nicosia. This shock, according to J. P. Rothé, of Strasbourg, was felt with intensity IX at Paralimni, thirteen miles from Famagusta (see also *Nature*, 148, 145 and 174 (1941); and 149, 640 (1942)). The depth of focus may have been 100 km. Shocks have occurred at other times from epicentres near Nicosia, near Limassol and at sea to the south of Paphos. Other epicentres have been at sea east of Cyprus (between Cyprus and Latakia). The line of past epicentres appears to stretch from Alexandria in Egypt to Nicosia in Cyprus and then to bend to the east, so that the present epicentre is somewhat north-west of this line.

Fifth British Mathematical Colloquium, Durham, 1953

The fifth British Mathematical Colloquium was held in Durham during September 8–10. Members were accommodated in University College and Hatfield College, and the main lectures were given in the Applebey Lecture Theatre of the recently opened Science Buildings. Analysis, topology and differential geometry, number theory and algebra were each given one day, the programmes being: September 8: J. L. B. Cooper, "Critical Point Methods of Functional Analysis"; J. D. Weston, "Convolution Algebras"; H. R. Pitt, "Convergence of Fourier Series"; September 9: J. H. C. Whitehead, "The Elements of Homotopy Theory"; M. G. Barratt, "The Calculation of Homotopy Groups"; A. H. Stone, "Coverings of Topological Spaces"; A. G. Walker, "Differential Geometry in the Large"; September 10: K. Mahler, "The Formal Approximation of Analytic Functions by Rational Functions"; E. M. Wright, "Problems about Prime Numbers"; R. A. Rankin, "The Minkowski–Hajós Theorem on Linear Forms and the Factorisation of Abelian Groups"; R. Rado, "Existence Combinatorics—Order in Chaos". In addition, 'splinter groups' displayed much enthusiasm in afternoon discussions of recent research topics in algebra, analysis, algebraic and differential geometry, topology and number theory. The stimulus of talks and debates on present-day activities in mathematical research was felt by all members of the Colloquium. The sixth Colloquium is to be held at Cambridge in April 1954.

Forests, Catchment Areas and Water Supplies throughout the World

Under the title of "Forests, Catchment Areas and Water Supplies" (*Indian Forest Records* (New Series), Silviculture, 7, No. 4, 258; 1952), a series of articles by Prof. E. P. Stebbing has been reprinted that originally appeared in a number of issues of the *Indian Forester* of the preceding months. The publication brings together information received in reply to a questionnaire sent out by Prof. Stebbing to forest services throughout the world, apart from Western Europe, and is prefaced by an introductory review covering sixteen pages setting out the reasons why the compilation was undertaken. This introduction aims at bringing out the need for fuller statistical information as a step towards fuller national and world recognition of urgently needed soil and water conservation measures, with particular reference to the part played by a forest cover; it collects useful and interesting data from scattered sources and reveals the critical situation which has been allowed to arise in the majority of countries. In the second part the statistical details given country by country and catchment by catchment can be of little interest except locally; but the descriptive notes of the history and present situation of forest denudation are often illuminating and of more general value. The publication should provide the conservationist with much useful ammunition in his campaign for public action in this vital field of water supplies.

Science at Christ's Hospital

THE recent celebration of the four hundredth anniversary of Christ's Hospital is marked by the publication of a quatercentenary number of the School's *Science Journal and N.H.S. Report*. This issue contains several articles having a historic flavour. M. Seakins writes of science four hundred years ago, that is, at the time that the School was founded. After referring to the scientific views of Paracelsus (who died twelve years before the signing of the charter of Christ's Hospital), the author deals in an interesting manner with other sixteenth-century pillars of science—chemists, physicists and biologists (who at that time devoted most of their attention to medicine). The founding of the Royal Mathematical School in 1673 is described by T. Dee. The proposal for such a School was originally made by Sir Robert Clayton and the idea was strongly supported by Pepys, whose work for naval education and reform is well known. The School, with a strong body of governors, was established within the framework of Christ's Hospital, and to-day it still provides places in Christ's Hospital for sons of naval officers. T. W. Hoskins, an Old Boy of Christ's Hospital, contributes an article showing how science, through the agency of the anatomist Prof. William Wright, and in collaboration with the historian Mr. Laurence Tanner, in 1933, tackled the problem of the identification of bones supposed to be those of the Princes in the Tower. Their findings are now well known to anthropologists and historians.

Other articles which assist in raising this school journal to a very high level of achievement include: "The Cutting of Gems" by A. E. Rouse; "Modern Weed Killers" by R. G. Hornung; "The Measurement of Strain" by D. J. Kluth; "Counting Butterflies" by M. G. Morris and C. J. Nunn; "Careers in Science and Engineering: (I) Royal Electrical and Mechanical Engineers" by Lieut. J. H. Tomkins (an Old Boy); "Evolution of Colour Photography" by C. L. Hicks; and "An Introduction to Diesel Engines" by N. S. Blake. Also included are the reports of the Entomological, Astronomical, Fishing and Bird Sections of the School's Natural History Society together with reports of other activities of that Society. Christ's Hospital, and especially the editor, J. M. Tims, are to be congratulated not only on this quatercentenary number of its *Science Journal* but also on the serious and successful part that science plays in the School's activities as revealed by the *Journal*.

Excavations at Mycenæ

A SUMMARY by Prof. A. J. B. Wace of his season of excavation last summer at Mycenæ, the most important city of Greece in the Late Bronze Age, has been published in the *Proceedings of the American Philosophical Society* (97, No. 3, 248; 1953). As is his habit, Prof. Wace has produced not only useful data for the specialists, but also more startling discoveries. Of these, there are a fine ivory facing, carved with a pair of griffins and originally half a metre or more in length; a terra-cotta figurine of a man riding a horse, which shows that, after all, the Mycenæan Greeks used horses for riding as well as drawing chariots; and thirty-eight clay tablets inscribed in the so-called Linear *B* script. These tablets, the first collection to be found at Mycenæ and the first from a private house anywhere in Greece, have turned up most opportunely, since it seems that at last the script is being deciphered. But too much should not be expected from their decipherment; it will show what language the Mycenæans spoke, but the texts may well give no more than inventories of stores or the like. Prof. Wace is continuing his excavation this season.

Arctic Aerobiology

QUANTITATIVE and qualitative studies of the fungi in the air over various parts of Alaska and Canada are reported by S. M. Pady and L. Kapica (*Canad. J. Bot.*, 31, 3, 309; 1953). In winter, arctic air is apparently sterile; in summer, at Ft. Churchill, Man., ground-level samples varied from 0·5 to 4·4 per cu. ft. *Cladosporium* was the commonest fungus (average 0·5 per cu. ft.), followed by yeasts (0·16), *Penicillium* (0·06), and *Stemphylium* (0·03 per cu. ft.). Other fungi present were *Pullularia*, *Botrytis*, *Aspergillus*, *Verticillium*, *Pyrenochaete*, *Helminthosporium*, *Phyllosticta*, *Papularia*, *Cunninghamella* and *Sporormia*. Of 3,711 colonies, 57 per cent failed to sporulate. Silicone slide readings as high as 114·9 fungus spores per cu. ft. were obtained and included the following: yeasts (8·6), *Cladosporium* (3·8), smuts (2·5), *Fusarium* (0·6), *Alternaria* (0·06 per cu. ft.), *Venturia*, *Cercospora*, *Septoria*, rusts, *Leptosphaeria*, *Sordaria* and *Pleospora*, and many hyaline one-celled spores. In two flights to Resolute Bay, N.W.T., the flora was found to be similar to that at Ft. Churchill, but numbers did not exceed 1 per cu. ft. although readings up to 78 fungus spores per cu. ft. were recorded on slides in warm air over Hudson Bay. Most of the fungi are considered to be soil types originating in agricultural areas and carried northward by southerly winds. The majority are no longer viable when they reach the arctic. There is evidence that the numbers of fungi are correlated with air masses, not only in the arctic but also in air over other parts of Canada.

Coryndon Memorial Museum, Nairobi: Report for 1952

THE annual report for 1952 of the Coryndon Memorial Museum, Nairobi (pp. 26; 1953; 1s.), though referring to the set-backs due to Mau Mau activities, also records the opening of a new wing. This important addition contains five new large exhibition halls which have been allocated respectively to botany; insects and allied forms; marine and freshwater biology and reptiles; geology, minerals and palæontology; and man. The new wing also contains a machine shop, a spirit room and extensive storage accommodation. Another interesting development at this well-known and progressive museum is that a loan was raised by the Government for the erection of a block of four flats. The flats are rented to members of the staff, and it is planned to repay interest and capital on the loan in twenty years.

Orientation of the Orbital Planes of Visual Binaries

CERTAIN conclusions are deduced by A. Opolski, of the Stockholm Observatory, with respect to the orbital planes of binaries on the basis of the distribution of slow-moving physical pairs with different apparent separations of components, and these conclusions are described in a paper entitled "Orientation of the Orbital Planes of the Visual Binaries" (*Arkiv för Astronomi*, 1, No. 18; 1952). Very briefly, the method is as follows. If we compare two slow-moving binaries, each of the brighter components having the same spectral type and the same apparent magnitude, and differing only in the apparent separation s of the components, it is very probable that such a pair of systems will have, on the average, equal absolute magnitudes, equal masses and equal distances from the sun. The difference in s in these circumstances is chiefly due to the difference in the inclinations i of their orbital planes. For obvious reasons, when s is small i is large—probably approaching 90°—and when s is large i is small—approaching 0°. All this is explicable because of the effect of perspective shortening, and for this reason there should be a correlation between s and i in groups of physical pairs with known dynamical parallaxes and with similar spectral types and apparent magnitudes. To obtain some idea of the validity of this assumption, all slow-moving physical pairs with their known trigonometric or spectroscopic parallaxes listed by Russell and Moore are dealt with. These stars are grouped according to spectral types and apparent magnitudes of brighter components and are arranged in each group according to s. Each group is then divided into three parts, each of which contains nearly the same number of stars, and two limiting values of separation s_1 and s_2 (s_1 being greater than s_2) are determined so that stars with separation $s > s_1$ form group i with small inclination, $s_1 > s > s_2$ form group ii, and $s_2 > s$ form group iii with large inclination. Numerical values of s_1 and s_2 are found in this way, and a comparison is made between the trigonometrical and dynamical parallaxes for stars belonging to groups i and iii. The stars selected for this purpose have their trigonometrical parallaxes t within the limits $0{\cdot}100'' > t \geqslant 0{\cdot}025''$, and the difference between the two mean values of dynamical parallaxes corresponding to the same mean trigonometrical parallaxes is very pronounced. This can be explained only by the systematic difference in inclination of the orbital planes of stars belonging to the groups i and iii, and substantiates Opolski's assumption.

Geographical Exploration To-day

THE Department of Extra Mural Studies of the University of London is arranging a series of twelve weekly illustrated lectures on "Geographical Exploration To-day", to be given in the Lecture Theatre, University College Medical School, London, W.C.1, on successive Wednesdays at 6.30 p.m., commencing September 30. The subjects to be dealt with and the respective lecturers are as follows: general introduction, by Prof. F. Debenham; arctic exploration, by J. M. Scott; antarctic exploration, by J. M. Wordie; exploration of the ocean depths, by Dr. G. E. R. Deacon; exploration in Central Africa, by Prof. F. Debenham; exploration in Ceylon, by B. H. Farmer; North-East Land, by Dr. K. S. Sandford; Cambridge Jontunheim expedition, by W. Vaughan Lewis; team-work in Colonial territories, by A. T. Grove; modern navigation by sea and air, by W. L. Harrison; exploring and climbing mountains, by J. H. Emlyn Jones; and exploring the past, by Prof. W. G. East. The fee for the course is 15*s.*; tickets for single lectures (obtainable at the lecture room on the occasion of each lecture) are 2*s.* Applications for admission tickets should be addressed to the Cashier, University of London, Senate House, Malet Street, W.C.1, and marked 'Extension courses'.

Announcements

DR. D. W. ADAMSON, head of the Chemical Division of the Wellcome Research Laboratories, Beckenham, has been appointed research director of the Wellcome Foundation, Ltd., and director of the Wellcome Research Laboratories, in succession to Dr. J. W. Trevan, who has retired after thirty-three years of service with the company. Dr. Adamson has also been appointed to the board of the Wellcome Foundation, Ltd.

IN his Pedler Lecture, "The Life and Times of Sir Richard Gregory, Bt., F.R.S., 1864–1952" (*Nature*, June 13, p. 1040), Sir Harold Hartley remarked that the Elihu Root Lecture given by Sir Richard Gregory at the Carnegie Institution of Washington and entitled "Cultural Contacts of Science" "is unknown in his own country". The substance of this Lecture was published in *Nature*, 142, 1059 (1938), and we are now informed by the Carnegie Institution that a limited number of copies of the Lecture are available free of charge.

THE British Institute of Recorded Sound, Ltd., in conjunction with the University of London, Department of Extra Mural Studies, is arranging a course of twelve lecture-recitals illustrating various uses of sound-recordings in the study of music, drama, literature and science. The three lectures with a bearing on scientific themes will be as follows: October 21, the sounds of wild animals and birds, by Ludwig Koch; January 13, folk music, by Frank Howes; and February 10, recording dialects and folklore, by David Abercrombie. All twelve lectures will be given on Wednesdays at fortnightly intervals, starting on October 7, at the Institut Français, Queensberry Place, London, S.W.7. The fee for the course is £1 (2*s.* 6*d.* a single lecture). All inquiries and applications should be made by post to the Honorary Secretary, British Institute of Recorded Sound, 36 Redcliffe Close, Old Brompton Road, London, S.W.5.

ERRATUM. In a letter on "Hæmoglobin in Protozoa" (*Nature*, Sept. 5, p. 451, col. 1) the sentence beginning on line 13 from the bottom should read: "Aerated suspensions of *Tetrahymena* showed a weak but distinct α-band of oxyhæmoglobin at about 582 mμ and a less distinct β-band at about 545 mμ which was somewhat masked by the absorption bands of cytochrome".

MEDIUM-ENERGY NUCLEAR PHYSICS

CONFERENCE AT THE UNIVERSITY OF PITTSBURGH

DURING June last, the University of Pittsburgh sponsored a second conference on medium-energy nuclear physics similar to that held in 1952. There were five sessions of invited papers intermingled with discussions. The first dealt with beta-decay, the second with nuclear forces and capture gamma-rays, the third with photon-induced reactions, the fourth with inelastic neutron scattering and nuclear energy-levels, and the final one with neutron-induced reactions.

The first paper, by L. Langer (Indiana University), discussed the evidence for a unique beta-interaction which can explain all known features of beta-decay. This includes the shape of the allowed and forbidden spectra, selection rules, the radium-*E* spectrum, and angular correlations between the emitted electron and the recoil nucleus. It seems likely that a linear combination of scalar, tensor, and perhaps some pseudoscalar can account for all known effects. In the second paper, M. E. Rose (Oak Ridge National Laboratory) indicated that even theoretically there are deviations from straight-line Kurie plots to be expected other than those due to Fierz interference. He suggested an experiment, the angular correlation in the $^{14}\text{O} \rightarrow {}^{14}\text{N}^*$ decay, which would definitely fix the nature of the Fermi-type interaction. In the third paper of the session, H. Primakoff (Washington University in St. Louis) reviewed the experimental evidence of Fulbright and McCarthy, and of Ingram and Reynolds for the existence and half-life of nuclei undergoing double beta-decay. The observed half-lives of zirconium-96 (10^{18} yr.) and of tellurium-130 (10^{21} yr.) make the effect difficult to detect. The theoretical estimates of such half-lives depend on the assumption of the existence of an anti-neutrino distinct from the neutrino or on the opposite assumption. The theoretical estimate is also difficult to make, but it appears that the no anti-neutrino hypothesis fits better. The decay of the μ-meson may be able to clarify the question.

The second session was opened by I. Talmi (Princeton University), who showed how the empirical rule that in even–even nuclei the spins and parities of excited states are either both odd or both even can be understood. It is necessary to use the fact that the potential is short-range, but then the result follows in both the Russell-Saunders and *j*-*j* coupling limits. The second paper was a review of the Butler theory of stripping reactions by E. Gerjuoy (University of Pittsburgh). This theory has been of great service in discovering the spin and parity of many nuclear-levels. It is not, however, in complete agreement with observed angular distributions. Arbitrariness in fitting the distribution could be reduced by comparing experimental and theoretical absolute differential cross-sections. However, the method of making allowance for Coulomb interactions is not at all clear. In the third paper, E. B. Paul (Chalk River Laboratory) spoke of his work on gamma-rays following proton capture. This work was done with the Chalk River electrostatic accelerator. The observed intensities of various gamma-rays of the same multiple order do not seem to accord with present theoretical expectations. The final paper of the session was a report by G. Bartholomew (Chalk River Laboratory) on work by B. B. Kinsey and himself with neutron captive gamma-rays. In particular, he discussed the great intensity of electric dipole radiation when the states were such as to permit it. Strong transitions to states other than the ground-state were found, where the information was sufficient, to be electric dipole.

The third session was opened by V. Telegdi (University of Chicago). He gave an account of the operation of isotopic spin selection rules in reactions induced by photons. The threshold energy of certain reactions, notably (γ,α) reactions, shows the operation of the conservation of total isotopic spin law. His experiments have been carried out with photographic plates. The other paper of this session was given by L. Katz (University of Saskatchewan). He reported on his work on reactions induced by photons from a betatron. In particular, he has studied neutron production, and has obtained indications of nuclear-levels by breaks in the yield-curve of neutrons as a function of photon energy.

The first three papers of the fourth session were devoted to inelastic neutron scattering. J. Beyster (Los Alamos Scientific Laboratory) described the spherical shell method for measuring inelastic neutron cross-sections. H. A. Bethe (Cornell University) discussed the interpretation of such experiments at energies where elastic scattering is large and nearly isotropic. The difficulty lies in the increased path-length in the shell due to elastic scattering. Methods for allowing for this which give values for inelastic scattering independent of experimental geometry were described. The resulting cross-sections vary as the geometrical cross-section except in the cases of the so-called magic nuclei, where they are smaller. T. Bonner (Rice Institute) described sphere measurements at higher neutron energies where the elastic scattering corrections are unimportant. The cross-sections turn out to be in good agreement with the geometrical cross-section except for the magic nuclei lead and bismuth, which are 10 per cent low. At low energy (∼ 3 MeV.) the cross-sections are less than the geometrical. R. Hellens (Westinghouse Electric Corp.) described some neutron scattering experiments on iron using photographic plates. F. Ajzenberg (Massachusetts Institute of Technology) closed the session with a comprehensive review of the energy-levels of light nuclei with especial emphasis on charge symmetry and charge independence of nuclear forces.

The last session was opened by H. Feshbach (Massachusetts Institute of Technology). He showed how the concept of the nuclear radius is at present ambiguous. Electron scattering, isotope shift, and μ-meson decay all measure the average electrostatic potential in the nucleus and all give results corresponding to a nuclear radius of $1{\cdot}2 \times 10^{-13} A^{1/3}$ cm. The binding energies of mirror nuclei, also affected by Coulomb forces, give $1{\cdot}45 \times 10^{-13} A^{1/3}$ cm. At present this cannot be reconciled. Next H. Barschall (University of Wisconsin) described the results of his work on the scattering of neutrons of heavy elements. The dependence of the cross-section for scattering on the incident energy and on the mass number has been determined over a wide range of these variables. This variation can be interpreted, as V. F. Weisskopf (Massachusetts Institute of Technology) explained in the next paper, on the 'cloudy crystal ball' model of the nucleus. The nucleus is represented by a potential with an imaginary part which represents absorption of the neutron. Adjustment of the depth, the radius (which is assumed to vary as $A^{1/3}$) and the absorption enables a very good fit to be obtained over the entire range of energy and mass. It may be possible to interpret the absorption in terms of the formation of a compound nucleus. The last paper was by C. Goodman (Massachusetts Institute of Technology), who presented some evidence of nuclear excitation by the electrostatic field of an incident proton.

PHILIP STEELE

AMERICAN AID FOR SCIENTIFIC AND INDUSTRIAL RESEARCH IN GREAT BRITAIN

FURTHER details of the proposed expenditure on advisory service, research and on education and training of the Counterpart Funds derived from United States Economic Aid under the Mutual Security Act of 1952, originally outlined in Cmd. 8776 of February 25, 1953, are given in a White Paper dated July 1953 (Programme of Expenditure of Counterpart Funds derived from United States Economic Aid. Cmd. 8918. Pp. 8. H.M.S.O. 4*d*. net). Under "Advisory Service", £25,000 goes to the Department of Scientific and Industrial Research for the development of advisory services in industrial engineering, and in the use of measurement techniques developed in the National Physical Laboratory, and a further £125,000 for assistance to research associations (in conjunction with trade associations where suitable) for the development or initiation of advisory services. A number of trade and employers' associations will receive grants totalling £72,000 in all to enable them to employ consultants on such subjects as cost accounting, factory lay-out and organization and the deployment of labour. The Ministry of Works receives £20,000 for the development of the Building Advisory Service, and the Ministry of Labour and National Service £15,000 for assistance to voluntary organizations developing advisory services to industry in the field of training. Agricultural departments will receive £116,500 for the extension or initiation of specific advisory services, and the British Institute of Management £35,000 for research and the preparation and provision of information of management subjects of importance to productivity and for the extension of the Institute's information and research departments.

Of £589,500 provisionally allocated for research, £210,000 goes to a programme of economic research based in part on proposals put forward by universities and research organizations. It includes £42,000 for studies of general factors affecting productivity and the adoption of innovations; £100,000 for studies in monopoly, competition and restrictive practices, including studies in the structure of selected industries; £25,000 for studies in the growth of capital and the finance of industry; £8,000 for studies of economic problems affecting labour recruitment and mobility; £11,000 for studies in economic problems of transport and £19,000 for studies in the statistical measurement of production. The programme of research in production economics, for which £75,000 is allocated, will be carried out under the ægis of the Department of Scientific and Industrial Research by research associations and other bodies. It will include studies of the innovation and development of new ideas; of the flow of scientific and technical information to industry and its relation to innovation and industrial efficiency; of the economics of re-equipment; and of the measurement of productivity and the causes of variation of industrial efficiency.

The programme of social research, for which £190,000 is allocated, will be planned and co-ordinated by the two Committees on Human Relations in Industry and Industrial Efficiency recently set up by the Lord President of the Council. It includes £20,000 for studies of the influence of equipment design and working conditions on the efficiency of operators; £15,000 for studies of factors affecting the efficient utilization of industrial engineering techniques; £30,000 for studies of factors influencing the effectiveness of incentive payment schemes; and £40,000 for studies of those restricting and facilitating the introduction of new production techniques and methods in industry; £30,000 for studies of the characteristics of management organizations influencing productivity; £10,000 for studies of factors facilitating the efficient utilization of university graduates in industry; and £25,000 for studies of promotion and training in industry. The allocation of £114,500 for research in agricultural subjects includes £8,000 each for studies in land ownership and in land economics; £25,000 for a survey of prevalence, etc., of livestock diseases, and £22,500 for studies of egg- and table-poultry production.

Of the £519,000 provisionally allocated for education and training, £290,000 is for the endowment of three university chairs or readerships in engineering and related subjects. It is hoped that one in heavy electrical engineering and another in production engineering will be at the Imperial College of Science and Technology, London. The £130,000 for technical education is for the creation of teaching posts in industrial engineering and the provision of scholarships in methods of engineering, work study and personnel management. Of £68,000 to agricultural departments, £25,000 is for postgraduate scholarships and a like sum for managerial and special courses for staffs of Co-operatives, £18,000 is for assistance to Scottish crofters, £20,000 is provided towards the development of engineering training facilities at Queen's University, Belfast, and the Belfast College of Technology, and £6,000 to the Department of Scientific and Industrial Research towards technical and management training in the cast iron industry.

The allocation for publicity includes £22,400 for publications, chiefly to the Department of Scientific and Industrial Research for the preparation of technical digests of articles appearing in the technical press, and the preparation of brochures on technical information services; and to research associations for the preparation of technical publications. An allocation is also being made to the Ministry of Works for the preparation of technical publications giving the results of scientific research and new developments in building. One million pounds has been allocated to the Revolving Loan Fund, £700,000 for loans to industry and £300,000 for loans to agriculture; advisory committees have been set up for each part of the fund. The types of loan likely to be approved and the conditions which will be attached to them will be announced by the committee for industry, of which Sir John Woods is chairman. Loans to agriculture (of which committee Sir Stanford Cooper is chairman) will be confined in the first instance to two main purposes: the provision of part of the approved capital cost of acquisition and installation of grain-drying equipment and storage facilities; and assistance in the provision of plant, equipment and working capital for agricultural co-operative societies and other approved associations of farmers.

AMERICAN PHILOSOPHICAL SOCIETY

YEAR BOOK FOR 1952

THE year book for 1952 of the American Philosophical Society* includes a brief history of the Society and a copy of the charter, together with the list of members and the customary obituary notices and list of publications during the year; besides this it gives, in the report of the committee on research, lists of grants made during the year January 1–December 31, 1952, from the three research funds administered by the Society as follows: from the Penrose Fund, which is unrestricted, 133 grants totalling 123,250 dollars; from the Johnson Fund, nine grants totalling 20,687 dollars; and from the Daland Fund, which is limited to research in clinical medicine, three grants totalling 3,750 dollars. Brief reports from recipients of grants, arranged alphabetically by sciences, are also included. Among the longer of these summaries may be mentioned those of the following: M. D. Taylor on the vapour-phase dissociation of formic, propionic and acetic acids, indicating that formic acid possesses by far the weakest hydrogen bond, acetic and propionic acids possessing bonds of nearly equal strength; R. W. Chaney, comparing the Cenozoic floras of Japan with those of corresponding age in North America, and indicating that *Metasequoia* was widely distributed and abundant at high northern latitudes during Cretaceous and Tertiary time; H. P. Hansen on his investigation of post-glacial forest migrations and climate in western Canada and Alaska by means of pollen analysis of peat sections; R. J. Drake on a study of the species (and distribution) of the non-marine mollusc fauna of Sonora (Mexico); W. B. Jackson on microclimatic factors in army ant behaviour and ecology; and A. Loveridge on ecological studies on the vanishing fauna of rain-forest remnants in tropical East Africa. F. A. McDermott reports further data on Jamaican Lampyridæ, M. C. Carlsen on plant collecting in southern Mexico and Honduras, H. A. Imshaug on a taxonomic and phytogeographic study of the lichen flora of the Rocky Mountains, Hui-Lin Li on a study of the Scrophulariaceæ of China, H. E. Moore, jun., on native and cultivated palms of the western hemisphere, and H. T. Skinner on character patterns in the American azaleas.

K. J. Hayes records an analysis of chimpanzee intelligence, and in biochemistry J. L. and E. M. Irvin report on their spectrophotometric study of the interaction of quinoline and acridine derivatives with plasma proteins, nucleic acids and nucleoproteins. W. J. Eversole summarizes studies which indicate a physiological role of secretions of the adrenal medullary hormones in water and electrolyte metabolism; G. R. Seaman, metabolic studies on the growth factor protogen; L. S. Cressman, studies on the prehistory of the Oregon coast; and M. I. Hilger, an ethnological field study of the beliefs, customs and traditions in the development, rearing and training of the Araucanian Indian child of Chile. Besides E. M. Kampa's investigation of the photosensitive pigments in marine animals in the vicinity of Bermuda, which indicates the observation of at least one new photosensitive pigment, there are briefer reports on eight other investigations by scientists working at the Bermuda Biological Station for Research, including aspects of phosphate metabolism, the luminous bacteria–bacteriophage system, the metabolic effects of sinus gland removal in land Crustacea, the sponges of Bermuda, cell-growth and development as affected by changes in oxidation-reduction potential, and parasitological studies of fishes.

STANDARD FREQUENCY TRANSMISSIONS FROM THE UNITED KINGDOM

STANDARDS of frequency and time differ from other standards of measurement in that they can be made available continuously over wide areas by means of radio transmissions. The frequencies of 2·5, 5, 10, 15, 20 and 25 Mc./s. have, by international agreement, been allocated for this purpose; and for several years past, a continuous service on all these frequencies (and also on 30 and 35 Mc./s.) has been operating from station *WWV* of the National Bureau of Standards, near Washington, D.C.

Such transmissions enable the user to standardize his equipment without costly and elaborate apparatus, but to be fully effective they must be received in all parts of the world. The *WWV* transmissions do not meet this requirement, and experiments on an international scale are therefore being conducted under the general direction of the International Radio Consultative Committee in order to discover the best means of securing world-wide coverage.

As the United Kingdom's contribution to this work, a limited programme of transmissions has been made daily since February 1950 from the Post Office station at Rugby under the call-sign *MSF*. On May 26 this year the programme was extended to provide a continuous (twenty-four hours a day) service of transmissions on the three frequencies of 2·5, 5 and 10 Mc./s. Later, 15 and 20 Mc./s. may be used, but only three frequencies will be transmitted simultaneously. The signals are identified by a speech announcement made at fifteen-minute intervals, while during five-minute periods the carrier waves are modulated in turn by a 1,000-c./s. tone and by 1-c./s. pulses, the fifty-ninth pulse in each minute being omitted. A supplementary local service for use within the United Kingdom is also provided by a special transmission at a frequency of 60 kc./s. for a period of one hour daily.

Full details of these new transmissions are given in a pamphlet issued by the National Physical Laboratory, Teddington, under the title "*MSF*—New Programme of Experimental Frequency Transmissions from the United Kingdom". The carrier and modulation frequencies are all obtained from the same standard and are maintained within ± 2 parts in 10^8 of their nominal values. The transmissions are regularly monitored at the National Physical Laboratory, and the results of daily measurements on

* American Philosophical Society. Year Book, 1952. January 1, 1952–December 31, 1952. Pp. 486+1 plate. (From the Society, Philadelphia, Penn., 1953.)

60 kc./s. are published monthly in the *Wireless Engineer*. Although the absolute frequency cannot be determined with certainty to better than one part in 10^8, relative values are known to one part in 10^9; and as the day-to-day stability is of interest to some users, the results are published to this accuracy.

These transmissions from the United Kingdom are interrupted during the interval 15–20 minutes past each hour so that one station alone can be measured under conditions where, for example, the signals from two stations such as *MSF* and *WWV* are being received at nearly equal strengths. This break in transmission will also permit measurements of radio noise to be made if no other transmission is present.

JOHN HENRY NEWMAN AND SCIENCE

DURING 1852 J. H. Newman delivered a series of lectures in University College, Dublin, which were known as "Discourses on the Scope and Nature of University Education". They are now usually read, as finally published in 1873, under the title of "The Idea of a University Defined and Illustrated". Newman founded the University College and was its first principal for some years. Opinions differ concerning the value of his work in Ireland—even Shane Leslie thought that it was a failure—but a series of lectures, given a century after Newman's endeavours to put before the Irish his ideas concerning the aims and functions of a university, were delivered by leading members of the staff of the institution which he founded and helped to create.

Prof. T. S. Wheeler* has dealt systematically and with commendable objectivity with Newman's views on the place of science in a university. Although Newman regarded the teaching of science and professional subjects as a duty of a university, nevertheless he considered the development of the mind the primary end of university education. His object was to form, particularly in his junior students, a cultivated intellect on which other knowledge could be grafted. Although Newman insisted that he had been fighting liberalism all his life, he intended his objections to concern the liberalism which was more recently known as rationalism or scientific humanism. He was a champion of a liberal education in the modern sense. A 'gentleman' was one who had been improved and sensitized by such an education (but even in his day Newman was not the only antagonist of the more partial of Locke's educational theories). Newman insisted that it is only the mind trained and developed by a liberal culture that can profitably absorb and utilize knowledge of all kinds. On one hand, we have to distrust the view that the liberally educated man can control everything—"a view that has flowered to its greatest exuberance in the Civil Service" (and is occasionally found in modern universities). On the other hand, we have to face the dangers which arise from over-specialization. Since Newman wrote, science has developed at an enormous rate. About a million scientific papers are published each year, and the scientist is overwhelmed by a flood of knowledge. As a result, there is more and more pressure of material for inclusion in a university course and an increasing tendency to specialization. The point of view of the average science graduate is narrow: neither at school nor at the university does he receive the training which Newman regarded as fundamental, except in rare cases. There is an increasing complaint that scientists know more and more about less and less, and that they are not always able to express themselves clearly by mouth and pen. If this is true, the disease is more apparent than the remedy; but it is satisfactory to note that in England most schools are trying to do something to overcome the intellectual narrowness of both their science and their arts students; and, if little has yet been done, the universities are at least aware of the needs.

Prof. Wheeler comments as follows: "In Newman's view the great object of a university is to make something or other of its students and not simply to protect the interests and advance the dominion of science. The modern estimate of the place of research in a university department of science is completely at variance with that of Newman; though he tended to modify these views later in life. At present, discovery is regarded as more important than teaching, and the standing of a science department is determined by the quality of the research work it produces rather than by the quality of its teaching. The plums in the academic profession go to the research worker. The good teacher seldom reaches the top". (In the modern university there is, of course, the 'good organizer' whose abilities and qualifications it is extremely difficult to define.)

Surprisingly, Newman was alive to the need for the development of teaching applied science in his University. The Great Exhibition of 1851 had shown that British industry was losing its premier place owing to the manner in which Continental nations were fostering applied science. The teaching of engineering, agriculture and medicine involves a practical as well as an academic approach and yet these subjects have been successfully incorporated in a university discipline.

Since the 'thirties of this century we have had theories, in spate, of the aims and nature of a university: we have had Allison Peers in "Red Brick", Moberly in "Post-War Crisis", the Harvard Report, Goodhart and Livingstone from an old university, Colonial and international conferences, the 'synthetics' of the Anglo-American peripatetics, and so on. In the midst of all this there is still something of relevance in the elegant writings of Newman.

STRUCTURAL BASIS OF THE CROSS-STRIATIONS IN MUSCLE

By DR. JEAN HANSON* and
DR. HUGH E. HUXLEY†

Department of Biology, Massachusetts Institute of Technology,
Cambridge, Massachusetts

THE myofibrils of striated muscle consist largely of protein (more than 90 per cent of their dry weight)[1], and it is believed[2] that the only proteins present in significant quantities are myosin, actin and probably a small amount of tropomyosin. We shall describe here evidence that the cross-striation of the myofibrils results from a discontinuous distribution of myosin along their length, the myosin being confined to the *A*-bands. Previous authors have tentatively suggested that this may be the case[3-6], but we believe that our evidence is more direct and conclusive than any previously presented.

---

* Fellow of the Rockefeller Foundation. On leave from the Medical Research Council Biophysics Research Unit, King's College, Strand, London, W.C.2.

† Fellow of the Commonwealth Fund. On leave from the Medical Research Council Unit for the Study of the Molecular Structure of Biological Systems, Cavendish Laboratory, Cambridge.

Methods have become available during recent years for extracting successively myosin and actin from muscle, with very little mutual contamination; minced fresh muscle in the form of broken fibres is used as the starting material. We have examined this material microscopically (in phase-contrast illumination, in polarized light and in the electron microscope) at various stages of extraction. We have also modified the procedures to permit their use on isolated myofibrils, where the whole process of extraction can be observed visually on the same single myofibril.

If minced rabbit muscle, before any extraction, is examined either by using normal histological sectioning procedures or else by fixing the material in formalin and fragmenting it to myofibrils in a Waring blendor, then the normal band pattern of relaxed muscle is seen. If, however, the muscle is examined after extraction for twenty minutes either by Guba–Straub solution (0·3 *M* KCl, 0·15 *M* phosphate buffer, *p*H 6·5) or by Hasselbach–Schneider[7] solution (0·47 *M* KCl, 0·01 *M* pyrophosphate, 0·1 *M* phosphate buffer, *p*H 6·4), then a new band pattern is seen. The *A*-band has largely disappeared, leaving only a narrow dark line which in favourable circumstances may be resolved into two fine lines lying on either side of the original *H*-band; the sarcomere-length is unchanged. Apart from the narrow dark band and the *Z*-line, the sarcomeres now have uniformly low density along their whole length and their birefringence has become very small or zero (cf. the *I*-band in normal muscle).

If the Hasselbach–Schneider procedure[7] for actin extraction is now carried out (the residue from the myosin extraction being broken up in a Waring blendor and stirred for eighteen hours with 0·6 *M* potassium chloride, *p*H > 6·0), the organized structure of the muscle disappears and only debris remains. Similarly, few fibrils can be recognized in the residue left after the use of Hasselbach and Schneider's method[7] for the simultaneous extraction of actin and myosin.

In order to observe these processes more closely, we have developed methods for carrying out analogous extractions on isolated myofibrils. Two types of fibrils were used: some were prepared by a modification of the method of Schick and Hass[8] ('trypsin-prepared fibrils') and others by breaking up bundles of glycerinated fibres[8] in a Waring blendor. A drop of a suspension of myofibrils is placed on a slide under a coverslip and observed in phase-contrast illumination or polarized light. Material from the *A*-band ('*A*-substance') is then removed from such myofibrils by irrigating the preparations with the following solutions: (1) Hasselbach–Schneider pyrophosphate solution plus 1 × 10^{-3} *M* $MgCl_2$; (2) Guba–Straub solution plus 4 × 10^{-4} *M* ATP. The *A*-substance disappears in 1–2 sec., leaving a fibril 'ghost', consisting of a faint 'backbone' with *Z*-lines and with a pair of lines on either side of each original *H*-band (Fig. 1); the fibrils are no longer distinguishably birefringent and, in contrast to their behaviour before extraction, they will no longer contract in 4 × 10^{-4} *M* ATP in 0·1 *M* KCl, 10^{-3} *M* $MgCl_2$. The loss of *A*-substance is accompanied by some swelling of the fibrils: if myofibrils are treated with Guba–Straub solution alone without ATP or with Hasselbach–Schneider's solution without magnesium, then swelling still occurs, but this time it is not accompanied by loss of *A*-substance or loss of birefringence.

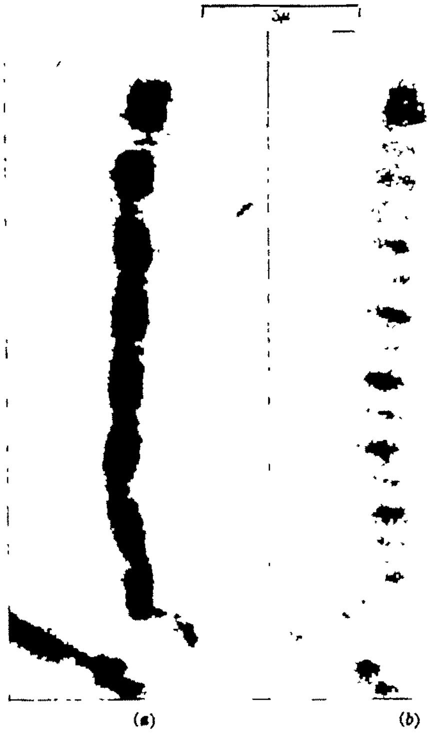

Fig. 1. Trypsin-prepared fibril under phase-contrast microscope, (a) before and (b) after extraction of *A*-substance by Guba–Straub–ATP

In the case of trypsin-prepared myofibrils, a slower secondary extraction process seems to occur, and the fibril ghosts become progressively fainter with longer treatment; if the extraction is carried out in a test-tube, then the ghosts apparently break up and dissolve, and no recognizable fragments can be recovered. It seems that these fibrils are unstable once the *A*-substance has been removed, and that any mechanical agitation will destroy them. This would account for the ease with which Hasselbach and Schneider[7] can extract actin when the residue from the myosin extraction is broken up in a Waring blendor. In the case of the glycerinated myofibrils, however, the ghosts are stable and may be recovered by centrifugation after a test-tube extraction. Examination of the supernatant in a Beckman ultra-violet spectrophotometer supports the view that protein-like material passes into solution during this extraction.

We have examined the 'ghost' fibrils in the electron microscope and compared them with normal fibrils. In the first instance this was done on unstained and unshadowed preparations, and it was found that the density distribution apparent under phase-contrast illumination in the light microscope was closely paralleled by that seen in the electron microscope. For more detailed examination, a thin-sectioning procedure was used; this technique has been described by Hodge, Huxley and Spiro[9] in a study of various types of intact muscle; the microtome used was that described by the same authors[10]. In these studies on intact muscle a hexagonal array of filaments about 100 A. in diameter was seen in the *A*-band, together with a good deal of interstitial

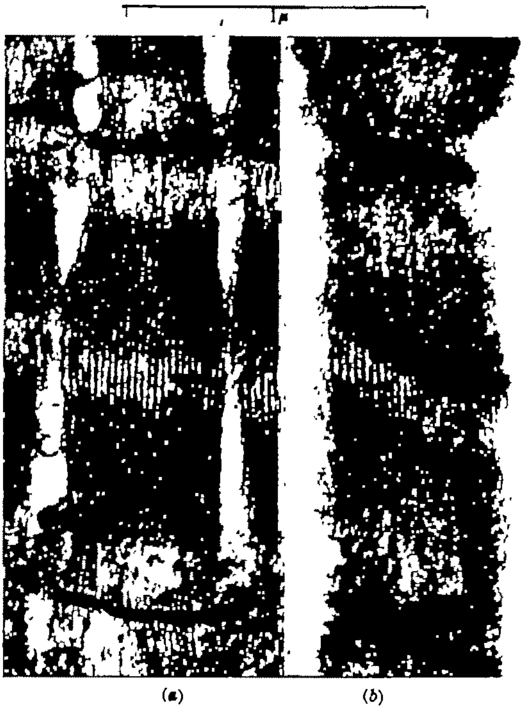

Fig. 2. Electron micrographs of thin sections through (a) intact glycerinated fibril and (b) glycerinated fibril after removal of *A*-substance by Guba-Straub-ATP

material. The *I*-band appeared to have been preserved less satisfactorily; it was much less dense than the *A*-band and contained much thinner filaments. Later studies by one of us (Huxley[11]) have shown that the interstitial material in the *A*-band itself consists of filaments, about 30–40 A. in diameter, and that in the absence of ATP these filaments are arranged in a regular six-fold array around each of the larger filaments. These observations confirmed the earlier predictions from low-angle X-ray diffraction studies[12]. It was also observed that the secondary six-fold array was absent from the *H*-band, where the diameter of the thicker filaments was about 130 A.

We find that, after extraction of the *A*-substance from isolated myofibrils by the methods described above, the thicker filaments which formed the primary array are no longer visible in the *A*-band, and that only fine filaments can now be seen; in the *H*-band, however, the thicker filaments are still present. The *Z*-lines and the thin dense bands on either side of the *H*-band are also visible (Fig. 2).

To summarize, we believe that the following evidence suggests very strongly that myosin is primarily concentrated in the *A*-bands in muscle and that it is responsible for the high density and the birefringence of these zones, and that actin is present as long filaments which extend continuously through *A*- and *I*-bands.

(*a*) Extraction procedures which are known to remove myosin and little or no actin from whole muscle remove a large amount of material from the *A*-band, and leave it with a low density and birefringence like that of the original *I*-band.

(*b*) If such extraction procedures are followed by the removal of actin, then the remainder of the organized structure of the muscle disappears, leaving only debris.

(*c*) If extraction procedures similar to those used to remove myosin from whole muscle are carried out on myofibrils, then the *A*-substance is removed, and the extraction can be viewed in a single myofibril in phase-contrast illumination or in polarized light. The material which passes into solution can be demonstrated to be protein-like by spectrophotometry.

(*d*) If such extraction procedures (carried out on trypsin-prepared myofibrils) are followed by mechanical agitation, then the fibril ghosts pass into solution.

(*e*) The *A*-bands of intact muscle, as seen in the electron-microscope, contain two sets of filaments. The larger filaments appear to have a total volume three to four times that of the smaller filaments: this is consistent with the view that the larger filaments are composed of myosin and the smaller ones of actin. After extraction of the *A*-substance, the larger filaments disappear.

We do not consider that observations of a shortening of the *I*-band during contraction necessarily imply that both actin and myosin are present there: such observations cannot at present distinguish between a genuine shortening of the filaments in the *A*-band, a migration of *A*-substance into the *I*-band, or a retraction of *I*-band filaments into the *A*-band.

In its simplest form, our picture of muscle is as follows: thin filaments of actin extend from the *Z*-line through the *I*-band and through one half of the *A*-band, until they join up with the *H*-band filaments, the composition of which is unknown. Myosin is located primarily in the *A*-band, in the form of filaments about 100 A. in diameter, which extend from the *A–I* junction up to the *H*-band, where they too join up with the *H*-band filaments. The myosin filaments are arranged in a continuous hexagonal array across the fibrils, with the actin filaments lying between them; in the absence of ATP, the actin filaments are linked to the myosin and form a regular six-fold array around each myosin filament. If the actin–myosin link is broken by the presence of ATP or pyrophosphate, the myosin filaments may be dissolved out from the muscle by solutions of suitable ionic strength, leaving behind a structure principally composed of actin.

We are at present pursuing experiments, similar to those described above, on muscle at various stages of contraction, in order to relate this concept of its structure to the mechanism of contraction.

We are greatly indebted to Prof. Francis O. Schmitt for the encouragement he has given to this research, and to the Rockefeller Foundation and the Commonwealth Fund for their support.

EVIDENCE OF HARMONICS IN THE SPECTRUM OF A SOLAR RADIO OUTBURST

By J. P. WILD, J. D. MURRAY and W. C. ROWE
Division of Radiophysics, Commonwealth Scientific and Industrial Research Organization, Australia

THE spectrum of the high-intensity radiation emitted by the disturbed sun at metre wavelengths is being investigated over a wide, continuous frequency-range extending from 38 to 220 Mc./s. The principle of the instrument follows that of an earlier model[1], but the extended frequency-range is achieved by using three swept-frequency receivers covering adjacent bands which are switched into operation in quick succession. Complete spectra are obtained every half-second and photographed on continuously moving film.

On November 21, 1952, at 23h. 50m. U.T., an outburst of radio noise from the sun was recorded on the instrument. The disturbance was accompanied by two flares both starting at 23h. 45m. (one of Importance 3, maximum at 23h. 50m. at 7° W., 6° N.; the other, Importance 2, 23h. 58m., 3° E., 6° N.), a magnetic disturbance, a short-wave communication fade-out, and a sudden diminishing of cosmic noise at frequencies up to about 70 Mc./s. The latter was registered on our record at 23h. 48·4m. and provides an accurate timing of the arrival of ultra-violet radiation relative to the outburst. (The information about the flares was received from Dr. M. Notuki, Tokyo Astronomical Observatory, and that on the magnetic disturbance from Mr. R. F. Thyer, Bureau of Mineral Resources, Melbourne.)

The dynamic spectrum is shown in Fig. 1a, in which intensity is indicated by two contour-levels as a function of frequency and time. At any instant the high-level radiation is received only in two widely spaced frequency bands, both of which exhibit the characteristic[2] frequency-drift from high to low frequencies. For much of the time each main band is split into two well-defined peaks of which the band-width, Δf, between half-power points may be as low as 2 Mc./s. When plotted on a logarithmic frequency-scale, as in Fig. 1a, the two main bands show a marked similarity in their general features and the two patterns appear to be essentially parallel. Thus the *ratio* of the frequencies of corresponding features in the two bands tends to remain constant. Corresponding features usually appear and disappear almost simultaneously. In view of their close correspondence, there seems little doubt that the two bands are due to the same source of emission.

The ratio between the frequencies of corresponding peaks lies mainly in the range 1·90–1·99, and in no case exceeds 2·00. For narrow band peaks ($\Delta f/f <$ 0·05) the ratio lies between 1·96 and 1·99; for broader peaks the ratio may be lower. Fig. 1b shows that if the frequency of a peak in the upper band is halved, the resulting point lies on the low-frequency slope of the corresponding peak in the lower band.

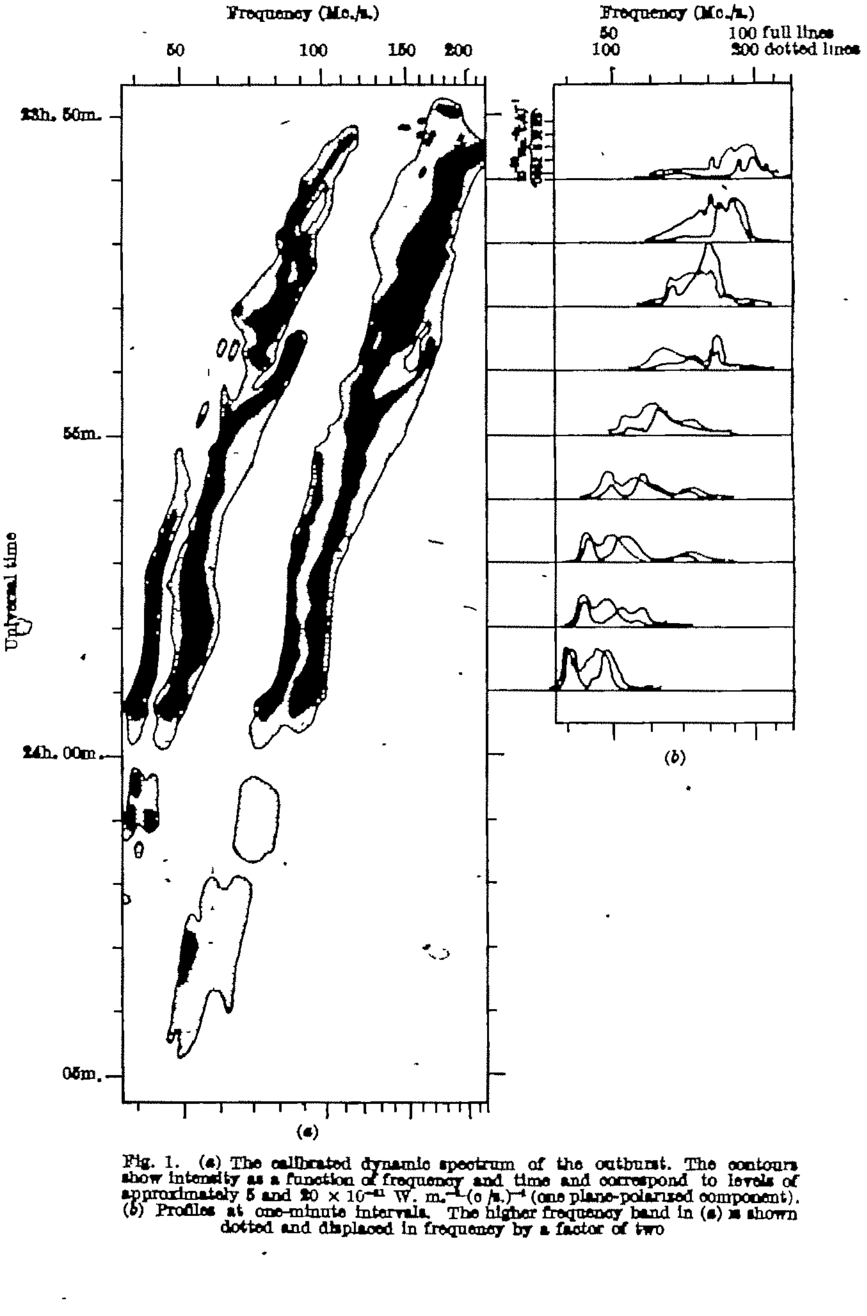

Fig. 1. (a) The calibrated dynamic spectrum of the outburst. The contours show intensity as a function of frequency and time and correspond to levels of approximately 5 and 20 × 10^{-21} W. $m.^{-2}$ $(c./s.)^{-1}$ (one plane-polarized component). (b) Profiles at one-minute intervals. The higher frequency band in (a) is shown dotted and displaced in frequency by a factor of two

The closeness of the ratio to 2 suggests that the two main bands are harmonically related. If this is so, two observed characteristics require explanation: (1) that the ratio is consistently slightly below 2·00; and (2) that the intensity of the presumed second harmonic is comparable with, or greater than, that of the fundamental, whereas the third harmonic, if radiated, must have been at least ten times weaker than the second.

The existence of a well-defined lowest frequency ('cut-off'), established by earlier observations of outburst spectra[2], led to the adoption of the hypothesis that the cut-off corresponds to the lowest frequency of escape at the level of the source in the solar corona, and that the frequency-drift corresponds to a movement of the source outwards through the corona. Neglecting magnetic fields, the 'lowest frequency of escape' from a source near the centre of the sun's disk is approximately equal to the natural plasma frequency[2], f_0. The occurrence of a sharp peak near the cut-off was associated with some kind of resonance phenomenon taking place near the f_0-level. If now we suppose that emission takes place at harmonic frequencies f_0, $2f_0$, . . ., in descending order of strength, the second and higher harmonics will reach the earth almost unattenuated, whereas frequencies close to f_0 will suffer highly selective absorption in their passage through the corona[3] (see Fig. 2). The rapid increase in absorption as the frequency is reduced through f_0 causes not only a diminishing of the peak-intensity but also a displacement of the peak-frequency by up to half a band-width. The close agreement between the result of this simple argument and the observed spectrum gives support to the conclusions (1) that the two main bands are harmonically related, and (2) that the radiation originates at the f_0-level.

The occurrence of multiple peaks within each main band could be due either to a multiple source or to splitting by magnetic fields. Taking the extreme low-frequency edge to indicate the height of the source, Fig. 3 shows the calculated variation of height with time. The heights are derived using a conversion table published by Smerd[4], based on the Baumbach–Allen distribution of electrons in the corona.

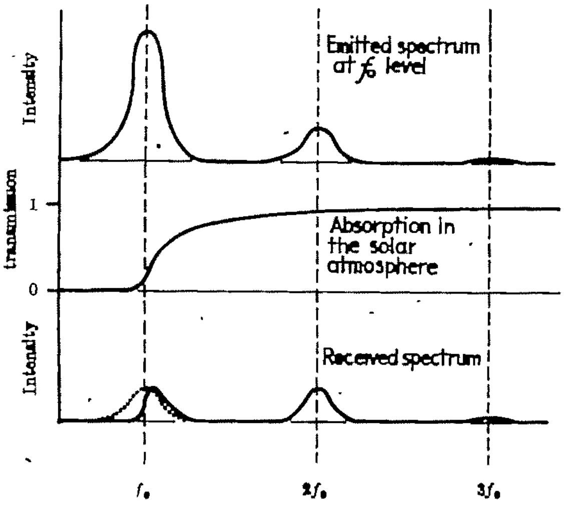

Fig. 2. Illustrating the effect of absorption in the solar atmosphere on harmonics emitted from the f_0-level. In the lowest curve, the second harmonic is reproduced with two-to-one frequency shift (dotted line)

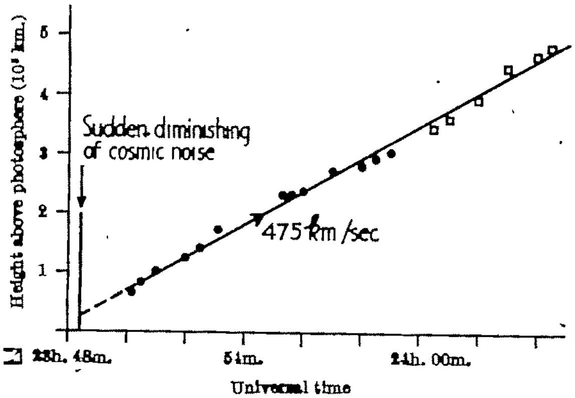

Fig. 3. Variation with time of the height of the source of the outburst according to the hypothesis described in the text. Where possible, heights are derived from the cut-off frequency of the lower band (black dots). The range is extended to greater heights by using half the frequency of the upper band (squares)

Apart from local deviations the gradient is constant throughout the curve, and corresponds to a velocity of 475 km./sec. It is of interest to note that if the constant-velocity line is produced towards the origin, the whole phenomenon could be explained in terms of a constant-velocity source ejected at the start of the ultra-violet emission from a region near the base of the corona, about $2 \cdot 5 \times 10^4$ km. above the photosphere.

The deduced velocity of 475 km./sec. agrees with previous values similarly derived[2], but the present data extend over a much wider range and give a clear indication that no acceleration occurred as the source moved outwards. Hence a real discrepancy exists between the derived velocity and the mean velocity (800–1,600 km./sec.) of the particles responsible for generating great magnetic storms on the earth, with which the source of outbursts has been tentatively identified[2]. Furthermore, Payne-Scott and Little[5] have derived velocities of 1,000–3,000 km./sec. from directional observations on outbursts. The discrepancy may be explained if, as suggested by recent evidence of Machin and Smith[6], the solar corona becomes much more extended than the Baumbach–Allen model for particular times and directions. It would disappear if the height scale in this model were increased by a factor of two to three.

[Feb. 10.

Note added in proof, August 11. The evidence presented above has recently been confirmed by a second outburst recorded on May 5, 1953, at about 5h. U.T. The spectrum showed two narrow bands which drifted in the usual way. The ratio of the peak frequencies lay in the range 1·93–2·00. No third harmonic was detected. The ratio of the peak intensities of the lower to the upper frequency bands varied between $\frac{1}{4}$ and 10.

Outbursts showing the characteristic spectrum but no detectable harmonic have been recorded on two occasions since observations were started in August 1952.

A MACROSCOPIC THEORY OF INTERFERENCE AND DIFFRACTION OF LIGHT FROM FINITE SOURCES

By Dr. E. WOLF

Department of Mathematical Physics, University of Edinburgh

IN the usual treatment of interference and diffraction of light, the source is assumed to be of vanishingly small dimensions (a point source), emitting strictly coherent radiation. Such a treatment corresponds essentially to an idealized wave field, created by a (classical) oscillator.

The important advances made in optics in recent years, in particular the discovery of phase contrast by Zernike[1] and of the method of reconstructed wave-fronts by Gabor[2], make it highly desirable to formulate a theory of interference and diffraction which applies to fields created by an actual (finite) source.

In papers to be published elsewhere, I propose a macroscopic theory of stationary fields produced by a finite source of natural, nearly monochromatic light. According to this theory, the intensity $I(x)$ in such a field can be expressed to a degree of accuracy sufficient for the purposes of many practical applications, in the form of a generalized Huygens's principle:

$$I(x) = \iint\limits_{\Sigma\Sigma} \Gamma(p_1,p_2)\tau(0,x_1)\tau(x_1,x)\tau^*(0,x_2)\tau^*(x_2,x) \, \Lambda_1\Lambda_2^* d\Sigma_1 d\Sigma_2. \quad (1)$$

Here Γ is a factor which characterizes the source, τ is a transmission function which characterizes the optical properties of the medium and Λ is the usual inclination factor of Huygens's principle. The integration is carried out twice independently over an arbitrary surface Σ cutting across the field, the ray vectors p_i ($i = 1, 2$) at the source being related to the position vectors x_i of points on Σ by means of the canonical relations:

$$p_i = \left[\frac{\partial}{\partial\xi} S(\xi, x_i)\right]_{\xi=0}, \quad (2)$$

S being Hamilton's point characteristic function of the medium. The factor Γ is related to the specific intensity $j(\xi)$ across the source σ (assumed to be a radiating plane element) by means of the relation

$$\Gamma(p_1,p_2) = \sqrt{\chi(p_1)\cos\theta_1}\sqrt{\chi(p_2)\cos\theta_2} \int\limits_{\sigma} j(\xi)\,[\exp ik\{(p_1-p_2).\xi\}]d\sigma, \quad (3)$$

the terms under the square roots being unessential directional factors, which in practice can usually be replaced by a constant, $k = 2\pi/\lambda$, λ being the wave-length. We normalise Γ, setting

$$\frac{\Gamma(p_1,p_2)}{\sqrt{\Gamma(p_1,p_1)}\sqrt{\Gamma(p_2,p_2)}} = \gamma(p_1-p_2). \quad (4)$$

It is seen that in (1) the properties of the source and the transmission of the medium are completely separated; also, that (1) contains only observable quantities, the non-observable phase factors which are associated with the instantaneous emissions of light having disappeared on taking the time average. Further, it is seen that the intensity distributions produced by different sources the Γ factor of which is the same are identical. This is probably the main reason why in Gabor's remarkable method of reconstructed wave-fronts one can use a different source for the reconstruction from that employed in taking the hologram.

Equations (3) and (4) enable γ to be calculated whenever the specific intensity distribution $j(\xi)$ across the radiating surface is known. It can also be shown that, under fairly general conditions, γ and consequently $j(\xi)$ may be determined from simple experiments.

Equations (1) and (3) make it possible to obtain solutions to a variety of optical problems. Although the theory is developed for radiation in the visible range of the spectrum, it seems probable that it will also apply to electron optics and perhaps also to the optics of X-rays. In the latter it may lead to a fuller interpretation of X-ray diffraction patterns of crystals. In astronomical applications the theory may enable information to be obtained about the distribution of radiation across stellar sources from the study of interference patterns (this question is discussed in forthcoming articles by R. Fürth and E. Finlay-Freundlich, and myself, to be published in "Vistas in Astronomy" (Pergamon Press, London)), a possibility which was recognized many years ago by Michelson[3] and recently pointed out again by Hopkins[4].

In the limiting case, as $\gamma \rightarrow 1$, (1) reduces to an expression for the intensity due to an ideal point source. Thus (1) contains the mathematical formulation of practically the whole elementary diffraction theory of optical image formation as a limiting case. It can also be shown that many of the results on partial coherence obtained by earlier authors (Berek[5], Van Cittert[6], Zernike[7], Hopkins[4]) also follow from our generalized formulation of Huygens's principle.

I am indebted to Prof. Max Born for stimulating and helpful discussions. [March 13.

SEISMIC REFRACTION EXPERIMENTS IN THE INDIAN OCEAN AND IN THE MEDITERRANEAN SEA

By Dr. T. F. GASKELL and J. C. SWALLOW

Dept. of Geodesy and Geophysics, University of Cambridge

THIS communication completes the preliminary account of results of seismic refraction experiments carried out in H.M.S. *Challenger* during her world cruise of 1950–52. Five stations in the Indian Ocean continue the deep-ocean studies described in two previous publications[1], and nine stations in various parts of the Mediterranean Sea give a measure of local underwater geological structure.

Indian Ocean

Fig. 1 shows the position of seismic stations in the Indian Ocean; Table 1 gives a summary of results.

Table 1

Station	Position	Depth (fm.)	Velocity in upper layer (ft./sec.)	Velocity in deep layer (ft./sec.)	Sediment thickness (ft.)	Upper layer thickness (ft.)
22	8° S. 95½° E.	2,805–2,855 (5·15–5·24 km.)	No upper layer	21,500 ± 500 (6·56 km./sec.)	1,500–2,500 (0·46–0·76 km.)	—
23	5½° S. 91½° E.	2,690–2,705 (4·94–4·96 km.)	16,500 ± 400 (5·03 km./sec.)	19,500 ± 1,000 (5·94 km./sec.)	500–1,800 (0·15–0·55 km.)	5,500 (1·68 km.)
24	4° S. 90° E.	1,655–1,710 (3·04–3·14 km.)	13,700 ± 200 (4·18 km./sec.)		1,200–2,400 (0·37–0·73 km.)	7,000 (2·14 km.)
25	3½° S. 86° E.	2,640–2,655 (4·84–4·87 km.)	14,500 ± 1,200 (4·42 km./sec.)	20,300 ± 1,200 (6·19 km./sec.)	1,800–2,600 (0·55–0·79 km.)	4,500 (1·37 km.)
26	2° S. 85° E.	2,550–2,580 (4·67–4·73 km.)	15,000 (4·57 km./sec.)	21,000 ± 2,000 (6·40 km./sec.)	6,000 (1·83 km.)	4,500 (1·37 km.)

At the Seychelles, a velocity of 7,000–9,000 ft./sec. (2·1–2·7 km./sec.) was found for a 90-ft. layer of coral rock. The velocity in the granite below this was 18,100 ft./sec., increasing to 19,700 ft./sec. (5·51–6·00 km./sec.); the refraction lines were limited to 1½ miles, and no deeper structure was found.

Station 22. This is in deep water outside the trench that lies to the seaward of Java and Sumatra. The structure here is similar to that found in the flat deep areas of the Pacific.

Station 24. This is on the top of a sea mount that rose about 6,000 ft. (1·83 km.) out of a very flat area of ocean bed. This area extended from 6° S. to within a hundred miles of Ceylon, and was flat to within a few fathoms per mile along the track followed by the ship, except for the large sea mount, and for a second small sea mount the sides of which sloped at about 1 in 5, and the top of which was a few hundred yards across.

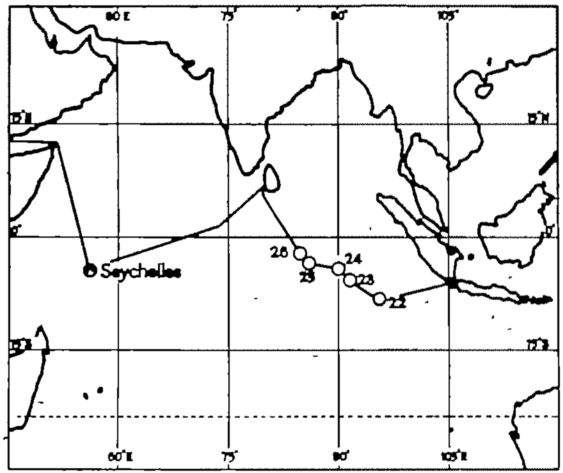

Fig. 1

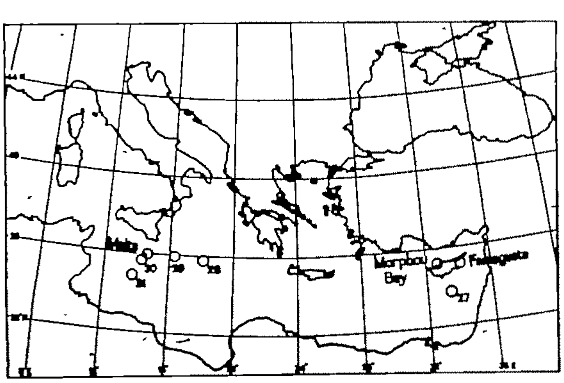

Fig. 2

The flat ocean area was much greater in extent than any other that had been sounded by the *Challenger*; it sloped upward from 2,700 fathoms (4·94 km.) in the south to 2,300 fathoms (4·21 km.) in the north. It was not possible to see from the echo-sounder record whether this slope was really a series of level steps or whether the average value of 1 in 2,000 was maintained throughout.

The depth over the top of the sea mount was irregular, and the velocity determined for the main constituent material could have been higher than the 13,700 ft./sec. (4·17 km./sec.) given in Table 1. The figure for minimum thickness of the 13,700 ft./sec. layer is calculated assuming that the underlying material has a velocity of sound of 21,000 ft./sec. (6·4 km./sec.). The thickness of sediment is variable, and is dependent on an undetermined velocity of sound, which, for all the Indian Ocean stations, has been taken as 7,000 ft./sec. (2·1 km./sec.).

Stations 23 *and* 25. At these stations a considerable thickness of material with velocities of 14,500–16,500 ft./sec. (4·4–5·0 km./sec.) was interposed between the sediment and the 'deep' layer. The velocity for the deep layer is less than that found at station 22, but if there is continuity of material, then this (4·4–5·0 km./sec.) layer is depressed well below the 3,000-fathom (5·5-km.) level at stations 23 and 25 adjacent to the sea mount; this structure is not unlike that found near Bermuda and, in the Pacific, near volcanic islands. It is possible, however, that north of station 22 the submarine geology is similar to that of the continents. At station 26 the velocity profile was not well determined, but the large part of the 6,000-ft. (1·8-km.) thickness of sediment was made up of a material with velocity 8,000 ft./sec. (2·4 km./sec.). Refraction lines of 30–40 miles (50–65 km.) will be needed to plot the depth of the Mohorovičić discontinuity in the Indian Ocean in order to determine the nature of the area to the north of lat. 6° S.; the present results are sufficient to indicate a difference in structure between north and south.

The Mediterranean Sea

Fig. 2 shows the positions of the nine stations at which measurements were made in the Mediterranean. The locations were chosen to assist the interpretation of gravity measurements made in 1950[1], but bad weather reduced the number of refraction lines possible leaving a rather isolated set of observations. However, the seismic data do suggest some grouping.

Stations 27, 28, 29, 31. All these stations show a single refracted wave the intercept of which corresponds to 1,200 ft. (0·36 km.) of sediment, and in which the velocity is about 14,500 ft./sec. (4·4 km./sec.). The thickness of sediment is calculated at an assumed

Table 2

Station	Position	Depth (fm.)	Depth (km.)	Velocity in upper layer (ft./sec.)	Velocity in upper layer (km./sec.)	Sediment thickness (ft.)	Sediment thickness (km.)
27	34° N. 23½° E.	1,080	1·98	14,300	4·36	1,100	0·33
28	36° N. 18° E.	2,175	3·98	15,000	4·57	1,200	0 37
29	36° N. 16° E.	1,940	3·54	14,500	4·42	1,200	0·37
31	35° N. 14° E.	196	0·36	14,900	4·54	2,600	0 97

value of 7,000 ft./sec. (2·1 km./sec.) except for station 31, where the shallower depth allowed observation of a layer with a velocity of 7,700 ft./sec. (2·3 km./sec.), 1,700 ft. (0·52 km.) thick beneath 900 ft. (0·27 km.) of material with (assumed) velocity of 6,000 ft./sec. (1·8 km./sec.). No layer with higher velocity was indicated by arrivals at nine miles for station 27 and for five to six miles at stations 28, 29 and 31. This could mean that the layer with velocity 14,500 ft./sec. (4·4 km./sec.) is more than 7,000 ft. (2·14 km.) thick at station 27, and more than 2,000 ft. (0·61 km.) thick at stations 28, 29 and 31, if the layer directly beneath has a velocity of 21,000 ft./sec. (6·4 km./sec.). However, the structure might also be a comparatively thin band of material with velocity 14,500 ft./sec. (4·4 km./sec.) underlain by a material with lower velocity; in order to produce a refracted wave at the distances given above, the band would probably have to be several hundred feet thick. (Results in East Anglia and in Persia suggest 100 ft. (0·03 km.) thickness of a limestone band for every 6,000 ft. (1·83 km.) of observable refracted wave.) If this is so, the fact that no refracted wave at 21,000 ft./sec. (6·4 km./sec.) was observed gives a minimum thickness of about 3,000 ft. (0·91 km.) of material with low velocity, beneath the band with velocity 14,500 ft./sec. (4·4 km./sec.) for station 27 and about half this thickness for stations 28, 29 and 31.

Cyprus. A detailed station, in 400 fathoms (0·73 km.), in Famagusta bay showed that a material of velocity 14,400 ft./sec. (4·39 km./sec.) was covered by 1,400 ft. (0·43 km.) of sediment the velocity in which was found to be 5,700–6,800 ft./sec. (1·74–2·07 km./sec.). At about four miles the refracted wave from this layer died out, suggesting that the layer was about 350 ft. (0·10 km.) thick, or that there was a horizontal discontinuity. A deep layer with velocity 22,000 ft./sec. (6·7 km./sec.) was detected 5,000 ft. (1·5 km.) below this, assuming a velocity 8,000 ft./sec. (2·4 km./sec.) between the 350 ft. thick layer and the material with velocity 22,000 ft./sec. If there were a horizontal discontinuity, the top of the 22,000 ft./sec. layer would be about 8,000 ft. (2·4 km.) below the sea surface. The high-velocity layer is several thousand feet, at least, nearer the sea surface than an undetected similar layer at station 27 could be.

At Morphou Bay, on the west side of Cyprus, the topography was very irregular, but some results in a depth of 75–140 fathoms (0·13–0·26 km.) showed that a rather irregular layer with velocity 9,700 ft./sec. (2·96 km./sec.) was covered with 1,900 ft. (0·58 km.) of sediment which had a well-measured velocity of 6,000 ft./sec. (1·8 km./sec.). Some refracted waves, arriving after those from the material with velocity 9,700 ft./sec., suggest that a layer with velocity 13,500 ft./sec. (4·1 km./sec.) lies 4,500–6,500 ft. (1·4–2·0 km.) below the sea-bed.

Malta. A short refraction line in 74 fathoms (0·13 km.) north of Malta (36° N., 14¼° E.) showed that 650 ft. (0·2 km.) of sediment, with a measured velocity of 5,440 ft./sec. (1·66 km./sec.), lay on top of material with velocity 11,400 ft./sec. (3·48 km./sec.). The latter would be greater than 2,000 ft. (0·6 km.) thick if it continued solidly to a material with velocity 18,000 ft./sec. (5·5 km./sec.). If it were a thin band underlain by a material with velocity 8,000 ft./sec. (2·4 km./sec.), the total thickness to a basement with a velocity of 21,000 ft./sec. (6·4 km./sec.) could not be less than 1,500 ft. (0·46 km.).

At station 30 (35½° N., 14¼° E.) the only refracted waves observed in 420 fathoms were from a material with velocity 18,750 ft./sec. (5·72 km./sec.). This was covered by about 1,200 ft. (0·36 km.) of sediment. The cover material could equally well be 200 ft. (0·06 km.) of sediment with velocity 5,440 ft./sec. (1·66 km./sec.), together with 2,200 ft. (0·67 km.) of material with velocity 11,400 ft./sec. (3·48 km./sec.). Measurements in the laboratory of velocities in limestones collected from Malta show values ranging from 9,300 to 19,000 ft./sec. (2·8–5·8 km./sec.).

The Mediterranean results in general show a more complicated structure than that found in the deep oceans. The existence of thin high-velocity layers is probable, which allows different interpretations of the seismic data. This does not mean that there is unlimited freedom in choosing a geological sequence, and a combination of gravity data and known geology on land may give an unambiguous picture. So far as possible the limiting values have been given in this account.

The fact that deep water obscures refracted waves from the sea-bed sediment layers leads to greater uncertainty in the Mediterranean than in the deep oceans, because in the latter the sediment is probably more uniform. In the deep-water stations (27, 28, 29), however, the sediment is about 1,200 ft. thick in all three cases, and it may be that these are far enough away from land for deep-ocean deposition conditions to exist.

The layer with velocity 14,500 ft./sec. (4·4 km./sec.) shows at many of the Mediterranean stations. It is probably the same material at the deep stations 28 and 29, and may be the same also at station 27, which is much shallower, but was also a flat area. The velocity is within the range of limestone, volcanic flows and many other well-compacted materials. Seismic measurements at greater distances will be able to provide additional information in the future, and the results given here should be of assistance in choosing critical areas for further work.

The work of H.M.S. *Challenger* has been carried out by kind permission of the Hydrographer of the Navy, with the support of the Ministry of Supply, and the willing co-operation of the officers and men in H.M.S. *Challenger* has made the work possible.

One of us (T. F. G.) is indebted to the chairman and directors of the Anglo-Iranian Oil Company for leave of absence to take part in the expedition.

Relation between Frank Spirals and Spiral Pits in Crystals

IN previous communications[1,2], the occurrence of spiral pits on crystals of some substances has been described. The phenomenon has been attributed to the presence of screw dislocations in the crystal, and a detailed analysis of the growth mechanism based on this assumption has been given[3,4]. It has also been suggested that, when a spiral pit is present on the upper surface, the lower surface should exhibit a Frank spiral (spiral hill)[5], at least when the dislocation line extends through the crystal plate[4]. It has now been possible to obtain strong evidence that this is indeed the case.

Crystals of potassium ferrocyanide, growing while floating on an aqueous solution of this substance, exhibit octagonal or square (sometimes hexagonal or lozenge-shaped) polygonized growth spiral pits which are, according to theory[4], turned over a small angle with respect to the periphery of the face (Figs. 1–4). By using monochromatic light and provided the crystals are sufficiently thin, fringes always appear at the centre of the spiral during growth, extend and leave the face. The interferometer is evidently formed by the upper and lower face of the crystal plate. Fig. 1, made by means of an ordinary metallographic microscope, shows a simple spiral and the fringe system centred on it, while Fig. 2, photographed somewhat later, shows the extension of the fringe system. The deviation of the fringes proves that there is a pit on the upper surface, and from it the step height can be measured. Fig. 3 shows two co-operating spirals (pits) on the upper surface, while the fringes reveal that, on the underneath surface, growth is starting on points situated exactly under the centres of the spirals. These observations allow us to conclude unambiguously that, on the underneath surface, growth takes place by means of layers which persistently spread out from a centre lying exactly under the centre of the spiral pit, which was assumed to be the emergence point of a screw dislocation. As the supersaturation is relatively high with the mode of growing used, individual layers are practically never resolved on the underneath surface. As it is, however, now well established that vicinal hills are, in fact, Frank spirals, we believe that our observations give very strong evidence that on the underneath surface growth proceeds by means of a Frank spiral centred on the same dislocation line as the spiral pit. Furthermore, Fig. 5 gives direct evidence that growth of these crystals can take place by means of Frank spirals. It is, moreover, now evident that Frank spirals and spiral pits have a common origin, that is, a dislocation.

This work is part of a research scheme supported by I.R.S.I.A. (C.E.S.). One of us (E. V.) is indebted to the Carbon and Carbide Corporation for a research fellowship. We thank Prof. W. Dekeyser for his continuous interest.

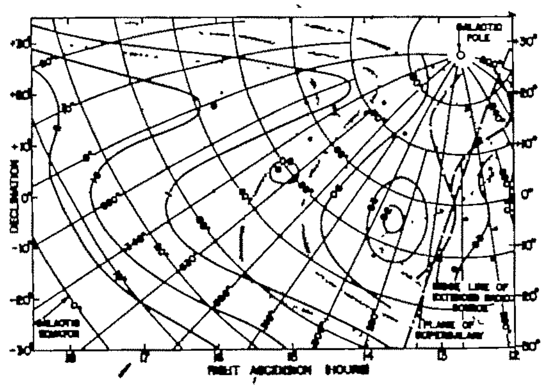
Radio Radiation from the Supergalaxy

IN March 1953, during a survey of the background radiation at 250 Mc./s. with the Ohio State radio telescope[1,2], a low-intensity source was observed near R.A. 13h. extending at least from Dec. − 15° to + 15°. Further measurements indicate that the maximum or ridge line of this source extends along the dashed curve shown in the accompanying figure. Near Dec. + 15° the ridge becomes double. The solid contours in the figure show the measured variation in background intensity at 250 Mc./s. Galactic co-ordinates are superposed on the figure, with celestial co-ordinates (1950.0) indicated along the edges.

An interesting feature of the extended source (shown by the dashed line) is that it corresponds approximately in position to the plane of our local supergalaxy described by de Vaucouleurs[3], and shown approximately in the figure by the dash–dot curve. The half-power width of the source is about 15° (in R.A.), which corresponds roughly to the width indicated by de Vaucouleurs. The radio intensity of the source rises above the background at Dec. − 5° by about 1 × 10^{-24} W.m.$^{-2}$ (c./s.)$^{-1}$/deg.$^{-2}$. These facts suggest the likelihood that the extended source is caused by radio radiation from our local supergalaxy (or galaxy of galaxies).



The solid curves are contours of cosmic radio noise (radio isophotes) measured at 250 Mc./s. Their absolute intensity is given approximately by the contour value multiplied by $1 \cdot 4 \times 10^{-24}$ W.m.$^{-2}$ (c./s.)$^{-1}$ deg.$^{-2}$

The solid dots in the figure give the locations of the dense clusters of galaxies from the map of Neyman, Scott and Shane[4].

Another noteworthy feature of the contour map is the long finger at Dec. + 20°, extending almost from the galactic equator to the galactic north pole. It has been observed also by Bolton and Westfold[5] in a survey at 100 Mc./s., and several of their extreme (lowest intensity) contours are here shown by the light dotted curves. It is not apparent from measurements to date whether this prominent feature is of galactic or extra-galactic origin.

The contours in the figure do not take into full account some gradual gradients in background intensity in both right ascension and declination. However, the positions of the essential features of the map are not affected by their presence.

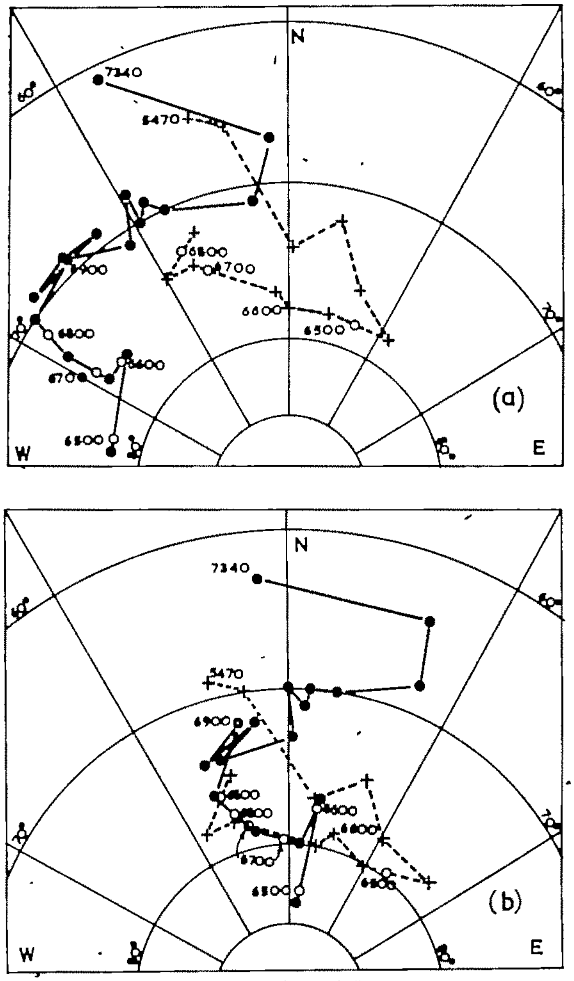
Remanent Magnetism of Varved Clays from Sweden

A RECENT discussion on the remanent magnetism of rocks[1] revealed that its origin is not yet fully understood. Some investigations[2] do, however, suggest that the polarization direction of sediments may be due to orientation in the earth's field during deposition of contained ferromagnetic particles. Such rocks may therefore provide information about the earth's field in past times. The measurements on Swedish varved clays described in this communication were made in order to test these ideas further.

Varved clays are laid down by rivers draining glaciated areas. Thus, in Scandinavia widespread deposition followed the Pleistocene Glaciation, and in northern areas deposition is still taking place at the present time. The clays show a marked lamination, the result of annual variation in the stream load. By means of the thickness variations of the layers, sections in different localities have been correlated and a record obtained covering several thousand years of deposition. This has been dated, and thus the age of any varve layer can be given.



Direction of remanent magnetism of Swedish varved clays: (a) uncorrected and (b) corrected for dip. Dates in years on Lidén's time scale where 7602 equals A.D. 1000. ●—●—, Prästmon; +−−+−−, Undrom; ○, interpolated points

In 1951, orientated specimens from varve series covering approximately the periods A.D. 1000–A.D. 0 and A.D. 500–500 B.C. were collected from Prästmon and Undrom, two localities about five miles apart in Ångermanland, Sweden. These varves were originally precisely dated by Lidén[3], but only an approximate correlation was obtained between the series collected, though the error was small. The polarization directions were measured with an A.C. magnetometer, a modified version of the apparatus described by Johnson[4].

These directions, plotted on a stereographic projection, are shown in Fig. (a), each point representing the average of five values. The mean deviations are 2°. It will be seen that there is considerable difference between the polarization directions for varves of the same age at the two localities. However, if the assumption is made that the layers were horizontal when deposited, and the magnetic vectors rotated to correct for the 3° dip of the beds at Undrom and the 12° dip at Prästmon, then quite close agreement is obtained between the two sets of values for points of corresponding age. The corrected values are shown in Fig. (b). The mean difference between the directions for the four interpolated points for the years 6500–6800 is, before correction, 13°; after correction, it is only 3°. The range of values when corrected is reasonable if secular variation of the earth's field is the cause of change.

This agreement is unlikely to be fortuitous, and the inference is therefore that the polarization direction was controlled by the earth's field during deposition of the sediment. It appears also from this agreement that the beds were laid down horizontally, a fact not supported by the geological evidence.

Further measurements on other material are being made. In co-operation with Swedish investigators, varves laid down during the past few hundred years have been obtained from a river delta using a non-magnetic core sampler. The polarization directions of these will be compared with observatory records of the earth's field for the corresponding period.

I am grateful to a number of people for advice and assistance, notably Prof. P. M. S. Blackett, Dr. S. K. Runcorn, Mr. R. F. King, and, in Sweden, Dr. Carl Caldenius of the Geological Survey, Prof. Gustav Ising and Mr. Lars Granar. I thank the Royal Society for a generous grant.

Generation of Weak Shock Waves

Because of the non-linearity of the pressure–volume relationship for air, different parts of a sound wave of finite amplitude propagate at different velocities. The wave distorts as it advances and shock fronts may be produced. Sound pulses which distort at a rate convenient for investigation of the phenomenon can be generated by discharging a condenser through the voice coil of a loudspeaker.

Fig. 1 shows the construction of the loudspeaker used. The cylindrical paper former carrying the voice coil *V* is glued to the aluminium diaphragm *D* and fits into the narrow gap of the magnet *M*. The rigid central portion of the diaphragm is in the shape of a shallow spherical cap and moves as a piston; the sound waves rapidly become plane in the propagation tube *T* of 1¼ in. diameter. The wave-form of the leading part of a typical pulse soon after generation is shown in Fig. 2; a choke in series with the voice coil prevents small irregularities in the waveform.

In the present case the maximum pressure that can be generated is determined by the mechanical strength of the voice coil and not, as in normal continuous working, by the efficiency of heat dissipation from the coil. With 240 volts on the 8 µF. condenser, a leading half-cycle of compression is produced with a peak pressure of 3 cm. mercury; the maximum peak pressure when the leading half-cycle is made one of rarefaction is somewhat less. The pulses are extremely reproducible when a mica condenser and a mercury switch are used. With other types of condenser the pressure amplitude of a pulse depends on the time of charging the condenser and other factors.

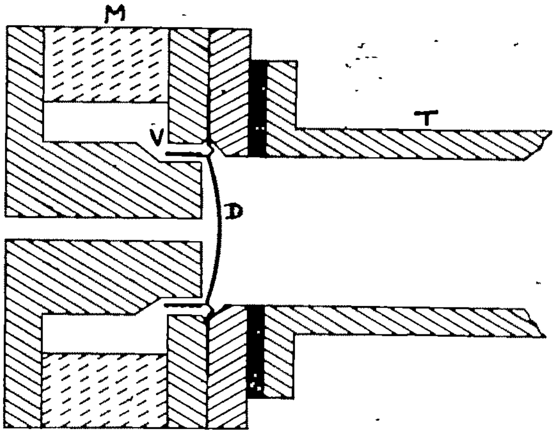

Fig. 1

Stokes[1] determined theoretically the distortion that would occur in a sound-wave, of given initial particle velocity–distance wave-form, under isothermal conditions. His construction, modified for a pressure-distance wave-form and adiabatic conditions, consists of drawing through any point *R* in the wave-form where the excess pressure is Δp, a line *RS* in the positive direction, parallel to the propagation axis, of length

$$c\,\frac{(\gamma + 1)}{2\gamma}\,\frac{\Delta p}{p}\,t,$$

where c is the velocity of sound of infinitesimal amplitude, p is the atmospheric pressure and γ is the ratio of the principal specific heats; the locus of the points *S* for all the values of Δp is the waveform after a time t. The construction is not valid beyond the point when a shock front is formed.

It has been shown experimentally by me, using a detector of uniform and high-frequency response[2], that the change in the shape of a sound pulse agrees

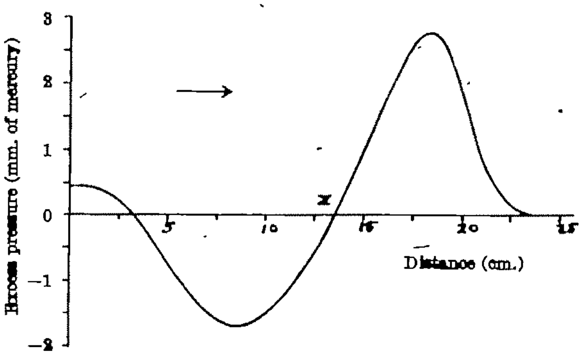

Fig. 2

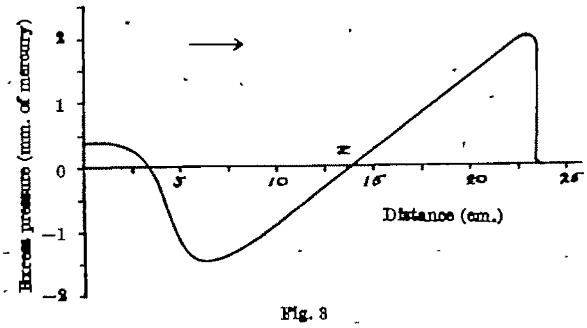

Fig. 3

closely with that predicted by this construction; the agreement with the theory (which neglects energy-dissipating agencies) is closest for pulses so strong that the distortion is rapid compared with the attenuation.

In general, a pulse eventually forms a shock front as in Fig. 3 (which is the pulse of Fig. 2, 6 millisec. later, that is, after propagation over a further 200 cm.). The velocity of propagation of the shock front of strength ΔP, relative to the point Z of zero excess pressure (which travels at velocity c), has been found to be slightly higher than the theoretical value

$$c \, \frac{(\gamma + 1)}{4\gamma} \, \frac{\Delta P}{p}$$

derived from Rankine's paper[3].

Nucleic Acid Template Hypotheses

IN a recent review and discussion of protein synthesis, Campbell and Work[1] have discussed a hypothesis for peptide chain synthesis published by me[2]; but in spite of rather favourable comments on this particular hypothesis, these authors have attempted to raise certain objections against the general concept that nucleic acids might be templates for protein synthesis. However, there seems to be a certain tendency to confuse nucleic acid template hypotheses with nuclear template hypotheses, where the word 'nuclear' refers to the nucleus of the cell.

In the hypothesis proposed by me, ribonucleic acid was deliberately chosen as the template, since it seems probable from a number of considerations and experimental investigations that protein synthesis may occur in cytoplasm as well as in nuclei. There can be no objection at the present time to assuming that the genes are templates, but it is not necessary to assume that the genes act directly as templates for protein synthesis. If we accept for the purposes of argument the suggestion of Mazia[3] that genes are composed of deoxyribonucleic acid, then it could conceivably happen that the deoxyribonucleic acid gene molecules would act as templates for ribonucleic acid synthesis, and that the ribonucleic acids synthesized on the gene templates would then in turn become templates for protein synthesis in the nucleus or cytoplasm or both. As a matter of fact, the recently discovered higher rate of turnover for nuclear than for cytoplasmic ribonucleic acid[4–10] would seem to lend some support to such an idea, as would the reported loss in cytoplasmic ribonucleic acid of amœbæ after denucleation[11,12]. However, a consideration of plasma genes and virus synthesis leads to the concept of an independent ribonucleic acid synthesis not involving nuclear genes. The concept expressed by Spiegelman and Kamen concerning the relationship between plasma genes and nuclear genes[13] could be explained by the template sequence deoxyribonucleic acid – ribonucleic acid – protein, with the additional postulate of a co-existing independent ribonucleic acid synthesis with ribonucleic acid acting as its own template.

Another objection raised by Campbell and Work against the participation of nucleic acid in protein synthesis is the lack of proved correlation between nucleic acid synthesis and protein synthesis. However, such lack of correlation is not an objection to the mechanism proposed by me, since a zero or inverse correlation could just as well be predicted, as can be inferred from what is said in the original article[2] concerning the ratio of substrates available in the cell for nucleic acid and for protein synthesis in a given time interval. There is no necessity for assuming any particular relationship between the rate of synthesis of a template and that of the product produced by the aid of this template. The only requirement is that the template be synthesized rapidly enough to be maintained at a suitable concentration in the cell.

If it is assumed that deoxyribonucleic acid has any function in the resting cell, it can be seen at once that such function could not correlate with deoxyribonucleic acid turnover, since the latter appears to be very low or zero in the resting cell. In fact, the maximum life-span of a resting cell might well be determined by the life-span of the deoxyribonucleic acid molecules contained therein, since all other types of molecules appear to have relatively high rates of turnover.

This note is by no means intended as an adverse criticism of the excellent review and discussion written by Campbell and Work, since it is obviously concerned with only one point in their article. The template hypothesis constructed by me was published mainly in the hope of promoting thinking and experimentation of a detailed nature concerned with the possibility that nucleic acids may participate in protein synthesis. It will be gratifying if this aim is achieved.

I am grateful to the National Cancer Institute of the National Institutes of Health for its support.

[13] Spiegelman, K., and Kamen, M., *Science*, 104, 581 (1946).

THERE is, we think, less difference of opinion between us than Dr. Dounce suggests. We took particular care to present the case for and against each current hypothesis, because we ourselves have no strong predilection for any theory and prefer at the present embryonic stage of the subject to keep an open mind.

Our paragraph headed "Objections to the Template Theory" was not intended to suggest that nucleic acids cannot act as templates for protein synthesis but rather to direct attention to the difficulty of any hypothesis which postulates a one-to-one relationship between genes and proteins. It is true, as suggested by Dr. Dounce, that there is no need to assume that genes act directly as templates; we can assume instead that genes synthesize ribonucleic acid templates and that these control protein synthesis. If, however, there were a specific gene for each ribonucleic acid template and a specific ribonucleic acid template for each protein, we should still have a one-to-one relationship between genes and proteins. It is particularly upon this concept of a one-to-one relationship between genes and proteins that we wished to cast doubt.

With regard to Dr. Dounce's second point, the correlation between rates of nucleic acid template synthesis and protein synthesis, we agree that it is not necessary to assume a direct proportionality between the two. It should be remembered, however, that much of the evidence for a relationship between nucleic acid synthesis and protein synthesis is based on experimental observations showing that under most conditions the two run closely parallel to one another. It seems to us illogical to accept this indirect evidence as support for the idea of participation of nucleic acids in protein synthesis, if, as suggested by Dr. Dounce, the theory does not in any case require a relationship between the rates of nucleic acid and protein synthesis.

Origin of Striations in Discharges

ALTERNATE dark and bright regions are a common feature of the positive column of a glow discharge in most gases. Such striations may be stationary or moving and the column will be uniform or striated depending upon the gas pressure, the current density and the radius of the tube. The existence of striations has been known for more than a century, but the mechanism of their appearance or absence is still obscure.

Stationary striations are generally attributed to some regularity which produces repetitions of the Faraday dark space. As a result of experiments, Donahue and Dieke[1] conclude that moving striations are due to regions of positive and negative space charge which travel towards the electrodes, and they suggest that the process is initiated by the accumulation of electrons in the negative glow region. On the other hand, Loeb[2] has suggested that the striations may be associated with plasma oscillations.

In the positive column of a discharge the electron and ion densities are substantially equal (that is, form a plasma), and under such conditions the charges may vibrate under the influence of the electrostatic forces. For electrons the frequency of oscillation has been calculated, with simplifying assumptions, to be 8,980 $n^{1/2}$ c./s., where n is the charge density, and frequencies of this order (for example, about 10^9 c./s.) have been observed[3]. If an electrical wave of sufficiently short length is propagated through the plasma and a standing wave set up, then striations may be accounted for by the positions of the nodes and antinodes. This mechanism would also account for moving striations, for the position of the standing wave system will depend upon the phase change on reflexion of the incident wave at the head of the column, and if the electron density there changes the striations will move. A sufficiently rapid movement will give rise to an apparently uniform column.

On this view of the mechanism the striations have their origin in the plasma itself, whereas on the other theories the effect is due to cathode phenomena. In order to investigate the matter, it is desirable to make observations under the simplest possible conditions. This may be done by using high-frequency excitation, so that the plasma is obtained in an isolated state. Due to the alternation of the field, there is no unidirectional loss of electrons (as in a D.C. discharge) so that secondary electron production is unnecessary and the cathode fall is absent. The conditions in the high-frequency glow are then similar to those in the D.C. positive column and the discharge is maintained at a low voltage. The high-frequency field is usually applied by means of sleeve electrodes wrapped on the outside of the tube, and stationary striations aligned along the axis of the tube and in the direction of the field have been observed in a number of gases[4]. Gale[5] has recently described striations obtained by placing a long discharge tube between the wires of a Lecher system. High-frequency glows were observed over regions corresponding to the voltage antinodes, and the striations in these glows were aligned along the axis of the tube, that is, at right angles to the field. Thus it appears that the direction of alignment of the striations is determined by the geometry of the plasma (that is, the shape of the tube) rather than by the direction of the exciting field. Any effect due to the electrodes may be eliminated if the electrodeless form of discharge is observed. In this case the electric field is induced by an alternating magnetic field and the glow is obtained in the form of a ring, and is, in effect, a plasma of infinite length. Striations in this form of glow have been described by Sir J. J. Thomson[6]. The bright and dark portions were radial, but were unsteady and flickered rapidly.

Thus the evidence presented by the occurrence and alignment of striations in high-frequency glows shows that they are a property of the plasma itself rather than due to a cathode mechanism, and supports the view that they may be due to a standing wave system associated with oscillations of the charges constituting the plasma.

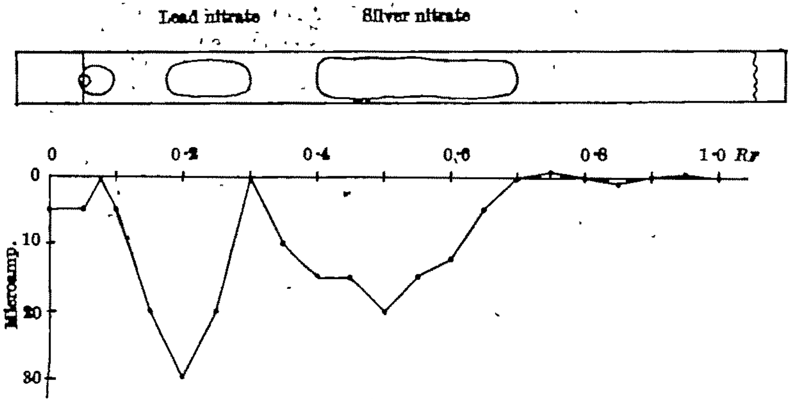
High-frequency Papyrography of Salts

A METHOD termed 'high-frequency papyrography', by which chemical substances and, in particular, electrolytes may be readily detected, has already been reported[1]. The process involves the movement of the papergram between the plates of a condenser in a tuned-grid-type high-frequency circuit, when large changes in the grid current are observed.



Solvent: butanol/pyridine/water, 100/20/20. Frequency: 15 Mc./s.

We have investigated the use of frequencies from 500 to 15,000 kc./s. and have found that the lower frequencies (500–5,000 kc./s.) promote greater sensitivity than the higher. We also find that each substance has an optimum frequency for maximum sensitivity. Further work is in progress in this direction.

The point of maximum concentration (required for calculation of R_F) is readily established (see diagram) by the apparatus even in the case of long spots caused by overlapping or tailing, and the sensitivity of the method is such that less than 1 γ of an inorganic compound can readily be detected. The sensitivity may be increased by the use of stronger currents.

It is essential that uniform filter paper should be used; any quantitative filter paper will become almost electrically uniform after electrolysis, as previously described[1]. However, precise quantitative results will not be obtained until a filter paper with less background 'noise' is available. To this end, the solvents used in the papergram must leave no residue, since the smaller the background 'noise' the higher the sensitivity. The results obtained are as illustrated.

We have investigated the use of electric conductometry at mains frequencies, but the results were inferior to those obtained using high-frequency currents.

Influence of Cations on the Ninhydrin Reaction for the Determination of Amino-Acids

The micro-determination of α-amino-acids with ninhydrin in *n*-butanol is highly sensitive, but often inaccurate due to the retardation of colour formation and the production of various red or blue colours instead of the purple compound usually obtained. It was found that traces of cations had a marked influence on the speed of colour formation and its intensity and on the absorption spectra of the coloured compounds produced. (The effect of cations on the ninhydrin colour was employed for the preservation of chromatogram spots by Kawerau and Wieland[1].)

The addition of 0·1 ml. of a *M*/100 solution of any of the cations, Al^{3+}, Hg^{2+}, Fe^{2+}, Fe^{3+}, Mn^{2+}, Sn^{2+}, Ag^{+} and Cu^{2+}, to a reaction mixture consisting of 10 μgm. alanine in 0·1 ml. water and 3 ml. of a 0·1 per cent solution of ninhydrin in *n*-butanol entirely abolished colour formation, which readily takes place when the reaction mixture is refluxed for ten minutes without the addition of cations. The presence of Ca^{2+}, Ba^{2+} and Cd^{2+} caused the formation of red colours with absorption maxima at 510 and 410 mμ (Ca^{2+} and Cd^{2+}) and 530 and 410 mμ (Ba^{2+}), which were spectrophotometrically detectable when about 1 μgm. of the cation was added to the reaction mixture. The absorption maximum of the normal colour at 570 mμ was progressively diminished and disappeared entirely when 20 μgm. of cation were present. The cation effect could be entirely eliminated by the addition of the chelating agent versene (the disodium salt of ethylene-tetraacetic acid). The coloured compound produced in its presence was uniform and had sharply defined absorption maxima at 570 and 410 mμ. The sensitivity of the reaction was considerably enhanced and exceeded that obtained by the addition of pyridine.

Good quantitative results could be obtained by employing the following method. A mixture, consisting of 0·1 ml. of the aqueous solution (containing 5–50 μgm. of the amino-acid to be determined), 0·3 ml. of a 0·3 per cent solution of versene in *M*/15 citrate buffer (*p*H = 5) and 3 mgm. ninhydrin dissolved in 3 ml. of aldehyde- and peroxide-free *n*-butanol, is refluxed for fifteen minutes in a 'Pyrex' reagent tube (20 × 250 mm.), using a cold finger condenser. After cooling, the mixture is diluted to 10 ml. with 50 per cent (v/v) ethanol and measured in any suitable photoelectric colorimeter at 570 mμ. The colour is stable for at least ten hours.

The method is easily adaptable for the evaluation of chromatogram spots. In this case, the spots should be located on the paper by one of the methods not employing the ninhydrin reaction[2]. The spots are cut out, the paper is cut into small pieces, added to the reaction mixture and treated as described above.

The method allowed the determination of the amino-acids glycine, valine, leucine, *iso*leucine, threonine, serine, lysine, arginine, histidine, glutamic acid, aspartic acid, tyrosine and methionine in the range of 0·3–4·0 gm. amino nitrogen, with an average accuracy of ± 3 per cent. The relation of optical density to concentration was linear over the same range.

Riboflavine and Thiamine Contents of Saffron, *Crocus sativus* Linn.

Four authenticated samples of saffron were analysed by us for the presence of riboflavine and thiamine by use of the spectrophotometer. An acetic acid buffer (*p*H 4·5) extract of saffron to which papain was added was taken. The pigment in the extract obtained (after destroying the enzyme papain by heating) was destroyed by addition of 10 ml. of 4 per cent potassium permanganate after adjusting the extract to *p*H 3·7 with glacial acetic acid. Hydrogen peroxide was added to destroy the excess of permanganate. The filtrate obtained was made up to volume and its fluorescence read on a spectrophotometer. The presence of fluorescing substances other than riboflavine was ruled out because on addition of sodium hydrosulphite solution in 0·2 *M* disodium phosphate, no fluorescence was observed, which would not have been the case had fluorescent substances other than riboflavine been present in the extract[1]. By treating an aliquot of the permanganate extract obtained above with alkaline potassium ferrocyanide and isobutyl alcohol, the thiamine was oxidized to thiochrome[2] which gets transferred to the isobutyl alcohol layer because of its greater solubility in that solvent. After drying this extract over anhydrous sodium sulphate, readings for thiamine were taken on the spectrophotometer.

The results of the analysis are presented in the accompanying table. Along with the results obtained for saffron, the riboflavine contents of other foods considered to be rich sources of this vitamin, and also some plant parts classed as spices, have been presented.

Product or plant	Plant part	Thiamine γ/gm.	Riboflavine γ/gm.	Authors
Saffron :				
Sample I		4·0	138	
„ II		3·8	93·3	
„ III		0·72	78·7	
„ IV		0·88	56·4	
Beta vulgaris	Leaves		20	Cheldelin and Williams, 1942
Spinacea oleracea	Leaves		22	Cheldelin and Williams, 1942
Cucurbita mexicana	Dry flowers		25	Cravioto *et al.*, 1945
Avena sativa	Coleoptile of embryo		20	Cravioto *et al.*, 1945
Ferula narthex	Gum resin from root			Aykroyd, 1951
Allium sativum	Bulb			Aykroyd, 1951
Myristica fragrans	Rind			Aykroyd, 1951
Marmite			33	Morton, 1942
Dry egg albumin			14·1	Morton, 1942
Dried yeast			30–50	Morton, 1942
Dried whey			20	Morton, 1942
Fresh ox liver			15·9	Morton, 1942
Calf liver			32	Elvehjem, 1943
Pork liver			27	Elvehjem, 1943

It will be noticed that saffron or the stigmas of *Crocus sativus* Linn. are easily the richest known source of vitamin B_2 or riboflavine. The thiamine or vitamin B_1 content is, however, insignificant.

High values for riboflavine contents of two of the saffron samples chemically analysed by us have also been secured by Dr. K. K. Iya and Mr. Sreenivasamurthy of the Indian Dairy Research Institute, Bangalore, who carried out the microbiological assay using *L. plantarum*-39 as the test organism. The authors are grateful to them for their kind co-operation.

Fibrinolysis by Adsorption

The plasma of normal people has been shown to contain a labile, active fibrinolysin[1,2,3]. Since this enzyme is not necessarily plasmin and in some ways behaves differently from plasmin, it has been tentatively termed 'plasma active fibrinolysin'[3]. The enzyme disappears rapidly from fluid blood and plasma kept at room temperature; but if blood is cooled immediately when taken and centrifuged at low temperature and the resultant plasma is diluted and clotted, lysis of the clots occurs within 24 hr. incubation at 37° C.[3]. Enzyme activity is insufficient to cause anything but slow and variable lysis of whole plasma clots[4]. Since lysis occurs on incubation, the enzyme is evidently stabilized once clotting has taken place, presumably by adsorption on fibrin. This suggested that pre-formed plasma clots might absorb the enzyme from fresh plasma. To investigate this possibility fifteen healthy individuals were studied. Citrated venous blood was obtained from each, and the resultant plasma kept at room temperature for 24 hours in order that all fibrinolytic activity should have disappeared. From this plasma, diluted 1 : 4 with a veronal saline buffer (*p*H 7·4), 1·0-ml. volume clots were made in small tubes by recalcification. The clots were ringed, removed from the tubes, and kept in normal saline for 2 hr.; clots made in this way do not retract appreciably, nor do they cause coagulation of added plasma. The subject was bled again, the blood being citrated and cooled immediately and then centrifuged at low temperature. Three of the clots described above were then placed in 3·0 ml. vol. of this plasma (fresh plasma) in tubes standing in ice and water. Adsorption was allowed to continue for 1 hr., the tubes being tilted every 2½ min. to ensure change of contact between clot and plasma. The clots were then washed thoroughly in saline. After the remainder of the plasma of the second bleeding had stood at room temperature for 4 hr., and had lost fibrinolytic activity, the above procedure was repeated exactly using this plasma (standing plasma) and three further clots. Control clots were placed in saline at 0° C. for 1 hr. The clots were then incubated in veronal saline buffer at 37° C. for 48 hr., and examined at intervals for lysis. Whereas no lysis of the clots treated with 'standing' plasma or of the controls occurred, on every occasion the clots treated with 'fresh' plasma underwent lysis of varying degree.

Further experiments showed that whole plasma clots made from silicone-taken blood (that is, no anticoagulant and no clotting agent were added) underwent considerable lysis on incubation after treatment with 'fresh' plasma but not after treatment with 4-hr. 'standing' plasma. Exercise of the subject before venepuncture increased the fibrinolytic effect of the plasma in which the clots were suspended. These data indicate that 'plasma active fibrinolysin' is present in undiluted plasma, from which it can be concentrated on a clot surface by adsorption. Since arterial thrombosis is initiated by the formation of a mural thrombus, an adsorbable fibrinolysin, if present in circulating blood, while insufficient to impair hæmostasis, could be augmented sufficiently by adsorption to have a thrombolytic and anti-thrombotic function.

Effect of Diuresis on Uptake of Radioiodine (^{131}I) by the Thyroid

In the past two years, radioiodine uptake has been studied in more than two hundred patients. From the analysis of our results, we are able to draw certain conclusions concerning the effect of diuresis on the urinary excretion of radioiodine. The iodine-131 was supplied from Harwell.

After administering the radioiodine to the subject, the urine is collected at frequent intervals for 104 hours. The usual tracer dose is 200 µC. while the average single effective dose is 5·5 mC. No special recommendations were given to the patients concerning the fluid intake. Fig. 1 shows the variation of the amount of iodine-131 excreted in urine during the first four hours as a function of the total water output during the same time. Patients are divided in groups following the total amount of the dose excreted. The water output varied from 50 c.c. to 750 c.c. Our results indicate that the uptake of radioiodine by human subjects is not affected by the diuresis, the latter being essentially dependent on the fluid intake.

Our observations indicate also a linear relationship between the percentage of the total dose of iodine excreted during four days and the amount excreted during the first four hours after administration. However, this observation is only valuable when we consider the mean values; the individual fluctuations observed are important because the variations are such that it is impossible to use this standard curve in order to determine the total uptake by the thyroid gland. It is to be noticed that the fluctuations are of less importance for patients with hyperthyroidism who excrete a low percentage of the dose. In the latter, the urinary excretion during the first four hours will give a rather good picture of the total uptake of the radioiodine.

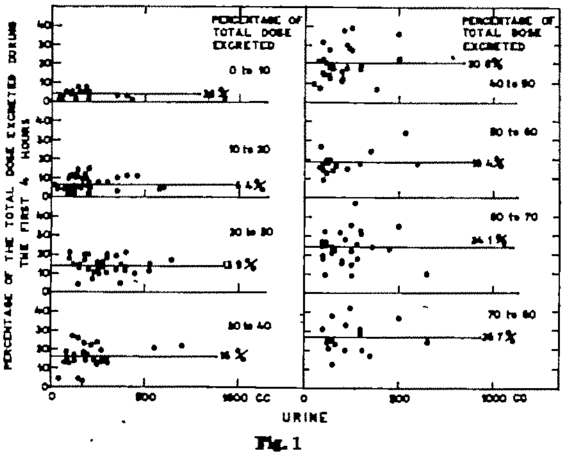

Fig. 1

So we may conclude that, in general, the urinary excretion of iodine-131 should be followed for a much longer time interval than four hours—an ideal time being forty-eight hours.

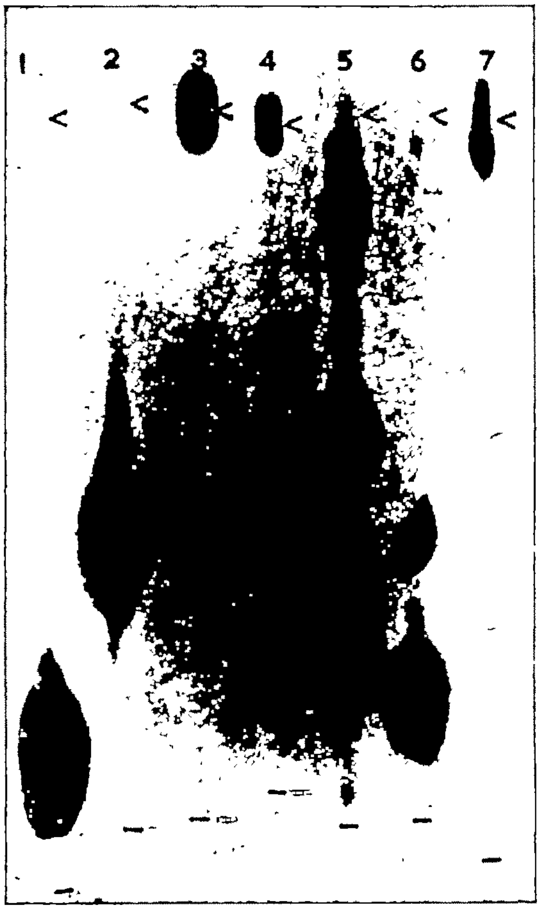
Hydrophilic Penicillins produced by *Penicillium chrysogenum*

It has been shown[1-3] that a species of *Cephalosporium* produces an antibacterial substance, cephalosporin *N*, which is a new type of penicillin characterized by its insolubility in most organic solvents and by a similar order of activity against Gram-positive and Gram-negative bacteria[4].

In the course of experiments, the results of which will be reported elsewhere, on the incidence of this type of hydrophilic penicillin production by moulds and factors controlling their biosynthesis, it has now been found that *Penicillium chrysogenum* produces a



(1) Benzyl penicillin. (2) *p*. Hydroxybenzyl penicillin. (3) Cephalosporin *N*. (4) Mixture of 1, 2 and 3. (5) Carbon eluate from *Penicillium chrysogenum* fermentation without phenylacetamide. (6) Carbon eluate from *Penicillium chrysogenum* fermentation with phenylacetamide (0·05 per cent). (7) Penicillin *N* from 5. <, point of origin on paper strips. —, solvent front

number of antibiotics more hydrophilic than *p.* hydroxybenzyl penicillin. Since these are readily destroyed by penicillinase it is concluded that they are penicillins.

P. chrysogenum Q176 was grown in deep aerated culture in corn steep liquor/lactose medium with and without phenyl acetamide (0·06 per cent). After 96 hr. the mycelium was filtered off and the filtrate adjusted to *p*H 6 before percolating it through columns of active carbon previously buffered with sodium phosphate (0·8 *M*) at *p*H 6. After washing the columns with water they were eluted with 50 per cent (v/v) acetone in water, when active material was recovered in a narrow band. After removal of the acetone, the active fractions were dried from the frozen state. Solutions of the powders were chromatographed by a modification of the method of Goodall and Levi[5], using paper strips buffered with sodium acetate (0·1 *M*) at *p*H 5·4 and developing with ethyl acetate, previously equilibrated with the buffer at room temperature (19–20°). After drying, the strips were placed on agar seeded with *Staph. aureus* 209P, removed after 30 min. and the plates incubated at 30°. The results of such chromatograms are shown in the accompanying figure. It will be seen that, in the absence of phenylacetamide, there is evidence of three antibiotic zones above the *p.* hydroxybenzyl zone: in the presence of phenylacetamide the zones due to the *p.* hydroxybenzyl and to the more hydrophilic penicillins are suppressed. Similar results were obtained in a number of similar fermentations.

The more solvent-soluble penicillins may be totally removed by exhaustive extraction with ethyl acetate from carbon eluates adjusted to *p*H 3, leaving a single antibiotic (penicillin *W*) in the aqueous phase which remains very near the point of application in chromatograms performed as described. This antibiotic, like the others, is rapidly destroyed by penicillinase.

Comparison of the relative activities of various penicillins against *Staph. aureus* 209P and *Klebsiella pneumoniae* (stock laboratory strain) using agar diffusion assay and cephalosporin *N* as standard gave results shown in the table. Of course, these relative activities must not be confused with absolute activities which can only be determined on the pure substances using dilution assays.

Penicillin	Apparent activity 'v' *Klebsiella* / Apparent activity 'v' *Staph. aureus*
Sodium benzyl penicillin	0·00092
Sodium *p.* hydroxybenzyl penicillin	0·0058
Penicillin *W*	0·162
Cephalosporin *N*	1·0

It is interesting, therefore, that penicillin *W* occupies a position intermediate between *p.* hydroxybenzyl penicillin and cephalosporin *N*. It should be emphasized that the hydrophilic penicillins described probably constitute only a small fraction of the total penicillins produced.

Depletion of Gamma Isomer of Benzene Hexachloride in Cattle Dipping-Fluids

Benzene hexachloride dips are highly effective for the control of cattle ticks and have been used extensively for this purpose. However, it was reported from South Africa[1] and Australia[2] that the toxicity of the fluid declined after the initial charging of the vat, even though chemical analyses indicated little loss in the content of benzene hexachloride. The methods of chemical analysis used in the investigations mentioned above were, however, not specific for the gamma isomer, and the assumption had to be made that its concentration maintained a constant relation to that of the total benzene hexachloride. This assumption has now been found to be unjustifiable, as estimation of the quantities of isomers in cattle dipping-fluids, rendered possible by the development of an appropriate method of adsorption chromatography[3], indicates a depletion of the gamma isomer in dips sufficiently marked to account for the observed loss of toxicity to ticks.

Dips for the control of *Boophilus microplus* in Queensland are usually charged at the rate of 500 parts per million of gamma benzene hexachloride. When engorged female ticks are dipped in this concentration of gamma isomer, almost 100 per cent fail to lay viable eggs. Fluid taken from a dip which was charged initially at 500 parts per million of the gamma isomer, and which had been in practical use for some time, was examined shortly after sampling. The gamma-isomer content was found by adsorption chromatography to be not more than 50 parts per million, and immersion in the fluid prevented only 41 per cent of female ticks from laying viable eggs. Samples from other dips in active use also showed depletion, the gamma-isomer content ranging from 80 to 150 parts per million. Marked reduction in gamma benzene hexachloride content also occurred in samples which were taken from dips containing 500 parts per million gamma isomer and stored in the laboratory for four years, one being found to contain not more than 0·5 part per million. Such samples produce practically no reduction in the number of females laying viable eggs. As there may be considerable variation in the rate of charging and replenishment of dips, and also as samples for analysis may not be representative, a clearer picture of the depletion of gamma isomer is obtained by expressing the amount present as a percentage of the total benzene hexachloride in the sample. In freshly prepared dipping-fluid the 500 parts per million gamma isomer represents approximately 12 per cent of the total, the values of 50–150 parts per million in fresh samples from dips in practical use, as mentioned above, represent 2·8–4·1 per cent, and in the sample which had been stored in the laboratory for four years the 0·5 part per million of gamma isomer that was recorded was only 0·02 per cent of the benzene hexachloride present.

The method of adsorption chromatography does not permit the separation of the gamma isomer from the small quantity of epsilon isomer present in technical benzene hexachloride[4]. The values of gamma isomer given above are therefore maxima, and, although there is probably also a loss of epsilon isomer in some samples, the possibility must be considered that there is even complete exhaustion of gamma isomer in some cases, the residue measured by chromatography consisting exclusively of epsilon isomer.

The satisfactory level of tick control achieved with most benzene hexachloride dips in spite of the differential loss of the most toxic isomer is doubtless accounted for by the use of the acaricide at a high initial concentration, and frequent replenishment with freshly prepared fluid to replace that removed by dipped animals. Reduction in toxicity of dips to female ticks does not become marked until the concentration of gamma isomer falls below 100 parts per million.

Further studies are in progress, and detailed results will be published elsewhere.

Non-Identity of Intermedin and Adrenocorticotrophic Hormone

It has been reported by Johnsson and Högberg[1] and Sulman[2] that some purified preparations of pituitary adrenocorticotrophic hormone have a strong dispersing action on the melanocytes of *Rana temporaria* and *Hyla arborea*, like the pituitary melanotropic hormone (intermedin), and from this and other arguments[1] they infer the identity of these hormones. However, later observations by Geschwindt *et al.*[3], Morris[4] and Lock[5] do not seem to be consistent with the hypothesis of Johnsson and Högberg[1] and Sulman[2], as (*a*) the melanotropic action of adrenocorticotrophic hormone could be separated from the corticotrophic, and (*b*) the treatment with 0·1 *N* alkali destroys the latter action to a large extent but leaves relatively unaffected or even potentiates the melanophore expanding action. If Johnsson and Högberg[1] and Sulman's[2] assumption were correct, highly purified preparations of intermedin would prevent, like adrenocorticotrophic hormone, the changes in the adrenals following hypophysectomy and restore the glands to their normal structure. In the toad *Bufo arenarum* Hensel, thirty days after complete removal of the pituitary, the adrenals appear atrophied, as the trabeculæ become thinner and the cortical cells lose most of the osmiophilic droplets (Fig. 1) observed in the normal controls (Fig. 2). If fifteen days after the hypophysectomy a daily injection of 100 μgm./100 gm. toad weight of adrenocorticotrophic hormone (from Armour and Co., lot *J*–80211) is started and continued for the following fifteen days, then the adrenals show again the thick trabecular structure and the cortical cells loaded with medium- and large-sized osmiophilic granula (Fig. 3). In the toads similarly injected with intermedin (LRW_1 extract of Landgrebe *et al.*[6]), the conditions of the adrenals (Fig. 4) is the same as in the hypophysectomized non-injected toads, which proves that intermedin cannot replace the action of adrenocorticotrophic hormone on the adrenals.

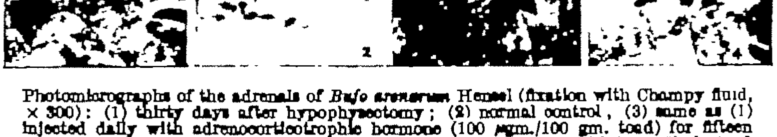
EFFECT OF INTERMEDIN AND ADRENOCORTICOTROPHIC HORMONE ON THE COLOUR OF *Bufo arenarum* HENSEL

The hormone preparation (0·1–0·5 ml.) was injected in the dorsal lymph-sac of pale (melanophore index: 1) hypophysectomized toads. Experiments in triplicate

	Amount of hormone (μgm./100 gm.)	Average maximal darkening	Average duration of darkening (hr.)
Intermedin	50	5·0*	102
Adrenocorticotrophic hormone	50	4·5	14
Intermedin	5	5·0	32
Adrenocorticotrophic hormone	5	1·0	0

* Melanophore index 5 corresponds to full dark colour, and 1 to complete paleness (cf. Hogben and Gordon[11]).

Both intermedin and adrenocorticotrophic hormone affect the colour of the *B. arenarum* Hensel. As is shown in the accompanying table, the pale skin of the hypophysectomized toads can be strongly darkened by intermedin and adrenocorticotrophic hormone, but the latter effect is shorter and weaker. The melanocytes of the *B. arenarum* Hensel seem to be more selective in their response to expanding agents than in other species (Stoppani[7]), and therefore their expansion by adrenocorticotrophic hormone may be well attributed to the presence of intermedin or a similar substance. This is confirmed by the increased melanotropic action of adrenocorticotrophic hormone after treatment with boiling 0·1 *N* sodium hydroxide for ten minutes, an effect which is typical of intermedin[8]. It must be pointed out that a preparation of adrenocorticotrophic hormone obtained by the method of Sayers *et al.*[9] from carefully dissected anterior lobes of ox pituitaries still showed melanophore-expanding properties. However, from the evidence summarized in this communication, it must be concluded that the melanotropic action of anterior pituitary extracts (or hormone preparations), which has been known since the earlier observations of Hogben[9] and Houssay and Ungar[10], does not invalidate the classical view that the melanotropic and adrenocorticotrophic actions of the hypophysis are due to different substances.



Photomicrographs of the adrenals of *Bufo arenarum* Hensel (fixation with Champy fluid, × 300): (1) thirty days after hypophysectomy; (2) normal control, (3) same as (1) injected daily with adrenocorticotrophic hormone (100 μgm./100 gm. toad) for fifteen days, starting fifteen days after hypophysectomy; (4) same as (3) but intermedin instead of adrenocorticotrophic hormone. Hæmatoxylin and eosin

We are indebted to Prof. J. Mendive for supplying samples of purified ox adrenocorticotrophic hormone.

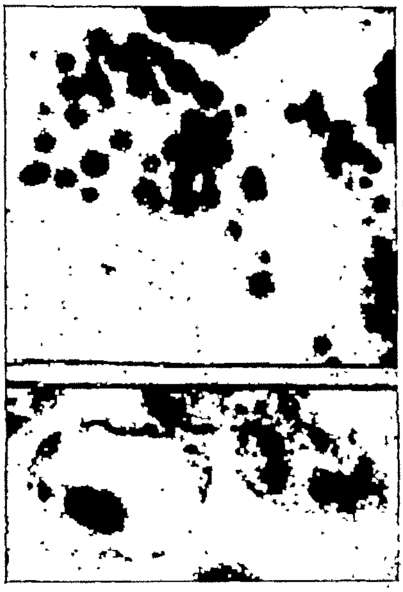
Origin and Fate of the Virus Bundles in Nuclear Polyhedroses

For a close study of the intranuclear cytology of sections of lepidopterous larvæ infected with nuclear polyhedral viruses, it is necessary, in addition to methods for staining the polyhedra[1], to have some method for staining the virus bundles which electron microscopy shows are embedded within the polyhedra. It has been found that this can be done readily, and the origin and fate of the virus bundles can then be traced. Owing to the limitations of ordinary light microscopy, the term virus bundle must perforce be used here to include not only bundles of mature virus rods, but also the bodies of a similar character which are liable to become embedded within polyhedra and within which virus rods may differentiate.

The virus bundles within the polyhedra are rendered visible by treating sections of Carnoy-fixed diseased animals with $1N$ HCl at 60° C. for 10 min., staining in diluted Giemsa for 20 hr., and differentiating in 95 per cent alcohol for 5–20 min. Each virus bundle within and without the polyhedra stains a deep reddish-purple and the polyhedral protein stains a weak pink colour. The distribution of the virus bundles within the smallest and largest polyhedra, the embedding of free virus bundles in already formed and growing polyhedra, the aggregation of polyhedral protein around groups of virus bundles to form polyhedra (as in *Lymantria dispar* and *L. monacha*), and the origin of the virus bundles in the chromatic material can all be readily made out. The species examined have been *L. dispar*, *L. monacha*, *Abraxas grossulariata*, *Panaxia dominula*, *Phlogophora meticulosa*, *Bombyx mori*, and *Ephestia cautella*.



(a) Polyhedra of *E. cautella* showing stained virus bundles within the polyhedra. Hydrochloric acid pretreatment followed by Giemsa. (× 1,750).
(b) Two diseased nuclei of *L. dispar*. One, prior to the formation of free virus bundles and polyhedra, shows a clear ring zone. The other shows developing polyhedra and free virus bundles between them. Hydrochloric acid pretreatment followed by Giemsa. Photographed with green filter. (× 1,750)

Prior to the formation of recognizable virus bundles and polyhedra in the nuclei of diseased cells, a ring zone devoid of chromatic material develops between the peripheral chromatin and the structureless central chromatic mass. Recognizable virus bundles form at about the time of the transformation of the chromatic mass to a network, and the bundles progressively detach themselves from the mass or strands of the net, where they form, to enter the ring zone. As the virus bundles differentiate from the chromatic material and become free, the strands of the network become greatly depleted in their staining capacity. Most of the freed virus bundles become embedded in the growing polyhedra. Some virus bundles also form in the peripheral chromatic material. No virus bundles have been observed, however, in the cytoplasm of infected cells with still intact nuclei.

The formation of polyhedra in *L. dispar* and *L. monacha* is somewhat atypical, many polyhedra arising from the deposition of polyhedral protein around aggregates of large and varying numbers of virus bundles. In these two species large and also small polyhedra may be found in any given nucleus just beginning to form polyhedra. In the other five species the usual course of events is for a more or less full complement of minute polyhedra, 0·2 μ–0·3 μ in size, to form, and for these polyhedra eventually to grow in size together. The very smallest polyhedra may contain one or no virus bundles, and as they grow, more and more virus bundles become embedded in them.

It may be remarked that the pictures of objects, unstained, within the polyhedra of *L. monacha*, as depicted by Komarek and Breindl[2] from Giemsa-stained material not pretreated with hydrochloric acid, can also be made out in completely unstained material. Though virus bundles can be made out in such material, nevertheless these authors saw far less than could be seen and also mistook diffraction effects as real objects. While Komarek and Breindl's pictures are misleading, the pictures of virus bundles obtained by the method described in this paper are identical in the size, number and distribution of the bundles with the electron microscope pictures of polyhedra lightly treated with alkali. This holds also for the polyhedra of *L. dispar*, *A. grossulariata*, *B. mori*, etc.

Other stains used in this work to stain the polyhedra, etc., have been mercuric bromophenol blue, Altmann's aniline acid fuchsin, methyl green, acid fuchsin followed by methyl green, and Schiff's reagent. The polyhedral virus attacking the economically important pest of stored products, *E. cautella*, was recently found by Dr. K. M. Smith and myself. Full details of the work will be published elsewhere.

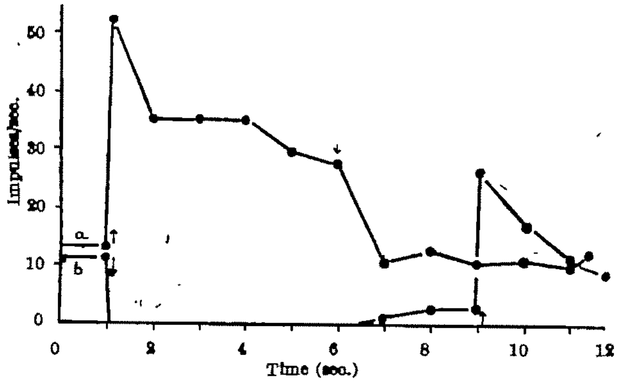
Effect of Galvanic Polarization on the Impulse Discharge from the Horizontal Ampulla of the Isolated Elasmobranch Labyrinth

EXPERIMENTS have been carried out on the isolated labyrinth of the elasmobranch fish *Raja clavata*, with the object of studying the effect of galvanic polarization on the behaviour of the sense endings in the crista of the horizontal semicircular canal. The electrical responses of this organ to rotatory stimulation have been fully analysed and described in previous papers[1,2]. Reference should be made to Lowenstein and Sand[1] for a detailed description of the method employed in making the physiological preparation and the oscillographic recording from the ampullary nerve.

This particular preparation offers a good opportunity to test some aspects of the 'generator potential hypothesis', according to which a galvanic potential intervenes between the mechanical deformation of the receptor cell or its associated auxiliary structures and the stream of discrete afferent impulses conducted along the sensory nerve[3-7].

By means of various devices, including an electronic high impedance D.C. stimulator, ascending and descending currents ranging from a fraction of a μamp. to a few μamp. were channelled through the strand of the sensory nerve from which the impulse responses were being recorded. The effects of such polarizing currents on the discharge activity of single sensory units are shown in the accompanying graph.



Impulse discharge rates from a single sensory unit of the horizontal canal crista in response to ascending (*a*) and descending (*b*) polarizing currents. Basic discharge rates 18 and 11 imp./sec. respectively. Arrows at make and break of polarizing current

The making of an ascending current flowing from the central end of the divided nerve strand towards the sensory epithelium causes an immediate rise in the basic rate of the impulse discharge (see trace *a*). During the period of maintained current flow, the discharge rate gradually falls (adaptation). Break of the ascending current usually produces post-excitatory depression of the discharge rate below the basic level, to which it finally returns (decay of the post-excitatory after-effect). This after-effect happened to be not very pronounced in the experiment illustrated in the graph. Descending currents have the opposite effect (see trace *b*). They cause marked inhibition to total abolition of the basic discharge. Adaptation during the maintained current flow leads to the gradual reappearance of the discharge activity, and the break of the descending current is followed by an instantaneous rise in the discharge rate above the basic level. The basic rate is finally restored by a decay of the post-inhibitory after-effect.

The behaviour of the sense ending is thus closely reminiscent of its response to natural rotatory stimulation, where rotation in opposite directions either increases or decreases the frequency of a basic discharge. Ascending and descending currents correspond in their excitatory and inhibitory effects to ipsi- and contralateral angular acceleration respectively. The agreement is complete and extends to the reproduction of the post-rotatory after-effects.

In the experiment illustrated by the graph the galvanic 'stimulus' was applied and removed by the action of a switch. It could, therefore, be suggested that we are dealing here with responses to cathodic or anodic make and break as such, and not to the continued flow of galvanic current. In order to remove this doubt, experiments were carried out in which the excitatory and inhibitory currents were slowly raised from sub-threshold to maximum, or where a smooth transition from maximum inhibitory current through zero to maximum stimulatory current and vice versa was effected by means of the electronic D.C. stimulator. Records so obtained showed quite unambiguously that the sense endings respond to a continuous change in polarizing current with a correspondingly smooth change in discharge frequency. The levels of activity correlated with various strengths of polarizing current are maintained for many minutes, but there is always a certain amount of 'adaptation' from the level attained immediately after the change in galvanic polarization.

It is clear from these results that D.C. polarization influences the vestibular discharge activity. The fact that this influence extends both to total inhibition of basic activity and to the evocation of impulse discharge in previously silent sensory units represents highly suggestive circumstantial evidence in favour of the assumption that such D.C. potentials could, in fact, be a physiological link in the chain of events taking place between the mechanical deformation of part of the sensory cell and the discharge of the train of discrete sensory impulses in the afferent nerve. It is also of interest that a basically silent sensory unit can be made to discharge as easily by the removal of an inhibitory current as by the imposition of an excitatory one.

With regard to the question of the localization of the galvanic effect, this may plausibly be assumed to take place at the end arborizations of the sensory nerve where they are applied in synaptic fashion to the cell bodies of the secondary sensory cells. This interpretation is also advocated by Katsuki[7] in his work on the effect of linearly rising currents on the lateral line end-organs. It now appears that there is a good case for applying the generator potential hypothesis to the whole of the vertebrate acustico-lateralis system, thus bringing the interpretation of its mode of function into line with that proposed by Granit and his co-workers for the retinal receptors or associated nervous structures in the eye.

Work on the quantitative analysis of stimulus response relationships with special reference to the adaptive behaviour of the end-organs is in progress. A full account of the results will be published elsewhere. The work was supported by a Royal Society Grant-in-aid of Scientific Investigations.

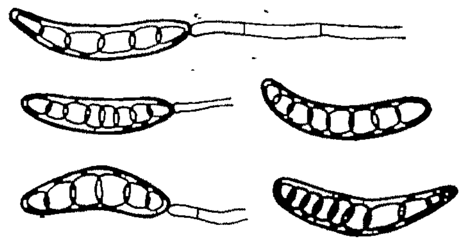
Occurrence in Nature of an Alternative Host (*Leersia hexandra* Sw.) of *Helminthosporium* oryzæ Breda de Haan

Helminthosporium oryzæ Breda de Haan, the causal organism of sesame leaf spot of paddy, has not yet been found to attack any other Graminaceous or other host plants in Nature with the single exception of *Oryza montana* from Togo reported by Roger[1]. Ocfemia[2] and Nisikado and Miyake[3] were able to obtain infection on a number of grasses under artificial conditions; similarly, Shaw[4] noted infection under artificial conditions of inoculation on maize, sorghum, oats and barley; Tochinai and Sakamoto[5] on maize, wheat, rye and barley; and Thomas[6] on *Elusine coracana*, *Pennisetum typhoides*, *Setaria italica*, oats, maize, wheat and sugar-cane.

In the course of search for an alternative host of *Helminthosporium oryzæ* in paddy fields at Chinsurah, we found a common perennial grass (*Leersia hexandra* Sw.) occurring in the bundhs of paddy fields with small oval spots of *Helminthosporium oryzæ* type measuring 0·5–3 mm. × 0·5 mm. in size, deep brown in colour with greyish centre, on the leaf blades. The bits of infected leaf blades when kept in sterile moist Petri dishes for forty-eight hours after surface sterilization developed conidia of the *Helminthosporium oryzæ* type measuring 33–125 μ × 9–19 μ with 5–9 septa, brown, straight to curved, cylindrical to elliptical, tapering towards both the ends, more so towards the apical end, without any prominent attachment region or hilum. They are borne on conidiophores measuring 150–350 μ in length and brown in colour.

The pathogen was isolated from the host in the usual way and monosporous cultures were made. Studies, under artificial conditions, of the culture were made to find out the relationship of the isolate from grass with *Helminthosporium oryzæ*. The isolate from the grass produced good mycelial growth on Richard's solution agar, oat agar and maize meal agar at 28–30° C. The mycelium was deep brown to black in colour with inconspicuous zonation. Conidia were formed on maize-meal agar. They were borne on conidiophores measuring 150–350 μ in length by 4–7 μ in breadth, dark brown in colour and arising as lateral branches from the vegetative hyphæ. Conidia were cylindrical to elliptical, straight to curved, widest at the middle, tapering towards both ends which were rounded, brown in colour, measuring 33–130 μ × 9–18 μ with 5–11 septa averaging 84 μ × 14·6 μ with 6–8 septa. Germination of the conidia was found to be bipolar, germ tubes arising from the two end-cells. Microscopic observations revealed the presence of hyphal fusions between the isolate from the grass (*Leersia hexandra* Sw.) and *Helminthosporium oryzæ* isolated from leaves of *Oryza sativa*, when grown beside it in 0·2 per cent agar on glass slide.



Helminthosporium oryzæ. Conidiophores and conidia from the infected leaf of the grass *Leersia hexandra* Sw., Chinsurah, West Bengal. (× c. 300)

Pathogenicity tests were carried out on both the grass (*Leersia hexandra* Sw.) and paddy (variety Bhasamanik) with the isolate from grass as well as with *Helminthosporium oryzæ* Breda de Haan, isolated from infected leaves of Asra variety of paddy at Chinsurah, West Bengal. On paddy the isolate from the grass readily produced infection. The spots produced were oval, younger ones being circular, deep brown in colour, with greyish centre, measuring 1–3·5 mm. × 0·5–1 mm. in size. On grass also, it produced similar infection. *Helminthosporium oryzæ* isolated from Asra paddy produced spots on the grass *Leersia hexandra* Sw., brown in colour, circular to oval in shape, measuring 1–2 mm. × 0·5–1 mm. in size—similar to those produced on Bhasamanik variety of paddy by the same fungus. Re-isolations made in each of the cases of cross-inoculation, namely, from both the grass *Leersia hexandra* Sw. and *Oryza sativa*, inoculated by both the isolate from the grass and *Helminthosporium oryzæ*, gave cultures identical to those used for infection.

Activity of the Incretory Centres of *Locustana pardalina* during Embryogenesis: Function of the Prothoracic Glands

EVINCED in insects is the existence of a tripartite endocrine system, and a composite hormonal mechanism. A brain factor liberated by the neurosecretory cells of the pars intercerebralis induces the prothoracic glands (ventral glands, pericardial glands, lateral cells or peritracheal glands of Weismann) to secrete their contributive hormone[1]. There is also abundant proof that the 'juvenile hormone' of the corpora allata promotes differentiation and growth in the larval direction[2]. However, there was much that still remained obscure about the particular function of the hormone secreted by the prothoracic glands.

The discovery of a pair of distinct glandular organs (prothoracic glands) in embryos of *Locustana pardalina* led to investigating the activity of the different incretory centres in relation to each other, and to the moult of provisional cuticle during embryogenesis.

Dried eggs of *Locustana* containing dormant embryos were wetted and kept at 30° C., 100 per cent relative humidity. Exposure to these conditions was responsible for a re-commencement of development. This was accompanied by a conspicuous enlargement of the neurosecretory cells. They maintained obvious histological signs of maximal secretory activity for 72 hr. After 96 hr., when katatrepsis was completed, their activity subsided, and thereafter it became practically impossible to distinguish them from ordinary nerve cells.

The prothoracic glands were first located with confidence on the completion of katatrepsis. They reached their maximal size and activity in the cycle 24 hr. later. The nuclei became more densely stained, and many of them became enlarged and slightly lobulated. However, the main point of interest was that this period of maximal activity of the glands coincided with the retraction of the epidermis from already formed cuticle. Thereafter, the glands became noticeably reduced in size, and at the time of emergence they were less than half their former peak size.

The corpora allata obtained their customary form and position on each side of the œsophagus in 96 hr. They showed no visible histological changes.

In view of the observed correlation between the maximal activity of the prothoracic glands and the embryonic moult, ligaturing tests were attempted on dissected-out embryos which had just completed katatrepsis. This was about 24 hr. before they were normally due to moult. The detached provisional cuticle resulting from the moult formed an easily detectable envelope. In four cases in a batch of twenty ligatured between the thorax and the abdomen, and examined 24 hr. later after being kept moist with isotonic solution, the thorax, but not the abdomen, moulted. Attempts to isolate the head gave uncertain results, but in two cases in a batch of twenty-two the body only appeared to moult.

Important conclusions to be drawn from the above evidence are as follows. First, the effectiveness of wetting the eggs terminating dormancy may be explained in terms of an action of moisture inducing the brain to liberate a developmental factor. Chilling the brain of the *Cecropia* silk-moth produces the same effect[1]. Secondly, the tissues were made competent to differentiate prior to the proper formation of either the prothoracic glands or the corpora allata. Thirdly, subsidence in the activity of the neurosecretory cells was followed by the prothoracic glands attaining their maximal size and activity. These glands appeared to be exclusively responsible for the retraction of the epidermis from its cuticle.

It is hoped to publish the details elsewhere with Mr. Sharan of this Department. Dr. Matthée, of the Agricultural Research Institute, Pretoria, very kindly made the locust egg-pods available for this work.

Sorghum Midge and Resistant Varieties in the Gold Coast

FAILURE of *Sorghum* to set seed has occasionally been noted in annual reports of the Gold Coast Agricultural Department, and attributed to climatic conditions. In view of the importance of this crop in the Northern Territories, investigations were commenced and have shown that this failure is due primarily to attacks by the sorghum midge, *Contarinia sorghicola* Coquillet.

Preliminary results from sample surveys showed increasing infestation as the flowering season progressed. A range of from approximately 20 per cent midge-infected grains in early-flowering varieties to 80 per cent in a late-flowering crop was recorded at the Nyankpala Agricultural Station, Tamale (9° 25′ N., 0° 95′ W.) in 1952. Comparable figures were obtained at Manga Agricultural Station, Bawku (11° 5′ N., 0° 15′ W.).

Variety plots indicated the value of early flowering as an escape from attack; but in addition one group of varieties showed apparent resistance. This group—of which Nunaba is the typical variety—has certain distinctive characters, including long papery glumes which do not normally open at anthesis. It appears that, as a result of this, the midge has difficulty in ovipositing within the glumes.

Sample counts showed 3 per cent infestation in Nunaba compared with 35 per cent in a variety which flowered normally at the same time.

A further result of the non-opening of the glumes is that natural hybridization rarely occurs. This character would have the additional practical advantage, therefore, of facilitating the maintenance of pure varieties.

The lack of natural hybrids may account for the fact that varieties with this character, which differ from one another only in minor details, are found only in the North-Eastern District of the Gold Coast.

In an effort to introduce the non-opening glume character into a wider range of types, a number of crosses have been made involving Nunaba and related varieties. It is difficult to collect pollen from these since the anthers remain enclosed within the glumes, but they may readily be used as female parents provided the glumes are clipped to expose the stigma immediately before pollination.

Heartwood Formation in *Pinus radiata* (D. Don)

In a paper which is to be published by the New Zealand Forest Service entitled "Heartwood Formation in *Pinus radiata*", it has been shown that conditions which are conducive to the occurrence of physiological drought retard heartwood formation in this species, but that where a deep root system can be developed in an area with adequate rainfall but without drying winds or low humidity heartwood formation is at a maximum. These findings are based on the statistical analysis of data from two hundred trees felled on twelve widely contrasted growing sites.

A further study of the bordered pits of wood tracheids in each growth layer from the cambium to the coloured heartwood suggests a mechanism whereby a maximum volume of sapwood would be retained to meet the demands of recurrent physiological drought. The percentage of bordered pits aspirated in a cross-sectional disk from a freshly felled tree is at a minimum (less than 5 per cent) in the outermost annual growth layers, and increases in a regular manner according to the number of growth layers to 50 per cent in the innermost layers of sapwood. In the zone of 'dry' wood (moisture content, 40 per cent) which characteristically surrounds the coloured heartwoods more than 95 per cent of the pits are aspirated, and this condition is maintained in the coloured heartwood. Thirty trees have been investigated in this way and observations made of some twelve thousand bordered pits. This distribution of aspirated pits is independent of site quality.

The degree of saturation of the wood, estimated from green and oven-dry measurements and the known fibre saturation point of the timber, is completely compatible with the concept that aspirated pits arise where a tracheid wall lies between one tracheid containing gas and one containing water. The degree of saturation in terms of pit aspiration must, of course, make due allowance for the fact that an isolated tracheid void of water influences the pits on two (radial) walls, whereas two contiguous voided tracheids cause aspiration of the pits of only three walls, the one wall being common to both tracheids. Thus 50 per cent pit aspiration implies 69 per cent saturation or that 31 per cent of the tracheids are devoid of water.

I am indebted to Mr. E. Lewis, biometrician at this Institute, for showing statistically that when more than 50 per cent of the pits are aspirated the apertures remaining open can no longer be considered to provide a continuous conducting system. If one accepts the findings of Stamm[1] that any openings which occur in the cell wall other than those present in the pit membrane are not of a size to provide passage for the penetration of liquids, it implies that the sapwood immediately contiguous to the heartwood is no longer a conducting system. The water in this tissue is therefore not subject to transpiration tension transmitted through the pits but becomes freely available to the living cells of the wood rays and epithelial cells of the resin canals for the hydrolysis of stored food which is lost in this zone.

It is suggested that during conditions of physiological drought when transpiration tensions are high the tension will not only be transmitted along the outer layers of sapwood which lie in a direct line between the transpiring leaves and the root hairs, but will also be transmitted with decreasing intensity across the resistance offered by successive growth layers and thence downward through the inner sapwood. While tension within the sapwood remains high the water is not freely available to the living cells. If, however, the tension in the outer layer of wood is not very great, the force is greatly reduced before many growth layers are crossed, and in this case the water in tracheids at a lesser distance from the cambium becomes freely available to the living cells. As this water is used, more bordered pits will become aspirated until eventually the critical point is reached when 50 per cent of the pits are aspirated, the free water remaining becomes readily available, and the central core of wood is 'dried out'. Absence of physiological drought therefore permits the acceleration of the processes leading to loss of water from the central core of wood, which is an essential first step in the formation of heartwood in pines, resulting as it does in the death of all cells and the accumulation of resins which undergo both physical and chemical changes during the formation of coloured heartwood.

Sterilization of Timber with Methyl Bromide

The effectiveness of methyl bromide as a fumigant for insect-infested timber has been reported by Burden and McMullen[1]. In view of its use as a fungicide for soil sterilization, it seemed desirable to investigate its value as a sterilizing agent for timber infected by staining and wood-destroying fungi.

Blocks of Norway spruce (*Picea abies* (L.) Karst), 5 in. by ½ in. by ½ in., were set in two inches of moist soil in large test-tubes which were then autoclaved at 15 lb. per sq. in. for 30 min. After inoculation with the test organisms (see accompanying table), duplicate series of blocks were incubated at room temperature for nine weeks. Good growth was obtained in all cases, no contamination being observed. The blocks were then subjected to a vacuum in a large desiccator (which procedure was found to have no adverse effect on the fungi) and a measured volume of methyl bromide introduced. Various combinations of gas concentration and fumigation time were used (see table). After fumigation, isolations were made from the wood blocks on to malt agar and incubated at 27° C. The plates were examined daily for a period of one month, and the results are shown in the accompanying table.

From the results obtained, the most effective treatment tested was 12 lb. per 1,000 cu.ft. for 96 hr.; but 20 lb. per 1,000 cu.ft. for 24 hr. also appeared moderately effective. In a preliminary experiment lower concentrations of methyl bromide were found to be ineffective against the test organism. No significant difference was noted in isolations made from either the surface or interior of the blocks. Similarly, no apparent difference was noted when the blocks were incubated for one week after fumigation as compared with isolates made within a few hours after treatment.

These results suggest the possible use of methyl bromide as a fumigant for the sterilization of fungal

infected timber, especially in large stocks or where heat treatment may be undesirable or impracticable. Since the discovery of Siricid wasp larvæ in imported timber during 1951, large-scale fumigation of timber with methyl bromide under plastic tarpaulins has been used extensively in Australia[2]. It should be emphasized that the process is one of sterilization rather than preservation. Further work on this project is not contemplated at present.

Testing of Two Samples

VARIOUS methods, parametric and non-parametric, are used for examining the significance of the difference between two given samples. The most common of these is the parametric one, the t-test[1], which is based on the assumption that the samples are drawn from a normal population. There is Pitman's[2] w-test which has been built up by considering all the possible samples that can be drawn by pooling together the two samples. Besides these, Wald and Wolfowitz[3] have used the run theory for deciding the significance of the difference between two samples. This method has been extended for k samples by myself[4]. Recently, tests have been constructed by Wallis[5], Kruskall[6] and Rijkoort[7] by using rank numbers for each of the samples.

It will be seen that the first method does not give any consideration to the order of occurrence of the individuals in the sample. The second, third and fourth methods mentioned above are based on the assumption that the probability for the occurrence of any individual depends only on the two samples together and do not take into account the magnitude and the relationship between the order of the individuals in the two samples. The object of this note is to give some tests which take both the above factors into consideration.

Suppose there are two samples of size n, the individuals of which take the values $\theta_1, \theta_2, \ldots \theta_k$ with probabilities $p_1, p_2 \ldots p_k$. Let the individuals of the samples, taken in the order of occurrence, be as follows:

$$\left.\begin{array}{lll} \text{Sample I} & x_1, x_2, \ldots & x_n \\ \text{Sample II} & y_1, y_2, \ldots & y_n \end{array}\right\}$$

Consider the distributions of X and Y defined by

$$X = \sum_{r=1}^{k} | x_r - y_r | ,$$

$$Y = \Sigma | x_r - y_r | + \Sigma | x_{r+1} - y_r | + \Sigma | x_r - y_{r+1} | .$$

The expectation and the variance of X and Y are as follows:

$$E(X) = n \sum_{r,s=1}^{k} | \theta_r - \theta_s | p_r p_s = n\varphi,$$

$$V(X) = n[\Sigma (\theta_r - \theta_s)^2 p_r p_s - \varphi^2] = nv,$$

$$E(Y) = (3n - 2)\varphi,$$

$$V(Y) = (3n - 2) v + 4 (3n - 4) [2\Sigma(| \theta_r - \theta_s | |\theta_s - \theta_t | + | \theta_r - \theta_t | | \theta_t - \theta_s | + | \theta_t - \theta_r | | \theta_r - \theta_s |) p_r p_s p_t + \Sigma(\theta_r - \theta_s)^2 p_r p_s (p_r + p_s) - \varphi^2].$$

The third and the fourth cumulants and, in fact, the higher cumulants of both X and Y can all be shown to be linear in n, the number of observations in the sample, and therefore the distributions tend to the normal form as n increases.

The two distributions considered here, and also their extensions, can be used for deciding whether two samples of moderate sizes can be considered as belonging to the same population. This can be done by comparing the standardized deviates of X and Y for the given samples, assuming the p's to be that obtained by pooling them together.

It may also be noted that it may be possible to have an optimum test by considering the distribution of

$$\left.\begin{array}{l} \Sigma | x_r - y_r | + \Sigma | x_{r+1} - y_r | \ldots \Sigma | x_{r+s} - y_r | \\ + \Sigma | x_r - y_{r+1} | + \Sigma | x_r - y_{r+2} | \ldots \Sigma | x_r - y_{r+s} | \end{array}\right\}$$

in which s will have to be so determined that the standardized deviate is a maximum. Also, instead of taking the p's as determined by pooling together the two samples, we may estimate them for given s by maximizing the standardized deviate.

It is hoped to discuss all these points in detail in a communication to be published elsewhere.

FORTHCOMING EVENTS

(*Meetings marked with an asterisk * are open to the public*)

Monday, September 21

Institute of Metal Finishing (at the Northampton Polytechnic, St. John Street, London, E.C.1), at 6 p.m.—Dr. J. Edwards: "The B.N.F. Jet Test on Organic Bright Nickel Deposits".

Tuesday, September 22

Society of Chemical Industry, Plastics and Polymer Group (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 6.30 p.m.—Prof. C. E. H. Bawn: "The Viscosity of Polymer Solutions".

Wednesday, September 23—Saturday, September 25

Society of Dyers and Colourists (at St. Annes-on-Sea).—Symposium on "Textile Printing".

Thursday, September 24

Television Society (at the Cinematograph Exhibitors' Association, 164 Shaftesbury Avenue, London, W.C.2), at 7 p.m.—Mr. D. D. Jones: "Transistors and Other Crystal Valves".

Friday, September 25

British Society of Rheology (in the Main Chemistry Lecture Theatre, Imperial College, Imperial Institute Road, London, S.W.7)—Symposium on "Mixing of Thick Liquids, Pastes and Slurries".*

Hospital Physicists' Association (in the Upper Lecture Theatre, Room 141, L Block, Hammersmith Hospital, Ducane Road, London, W.12), at 8.15 p.m.—Dr. A. Glucksmann: "Radiosensitivity at Different Levels of Biological Complexity" (Third Douglas Lea Memorial Lecture).*

Saturday, September 26

Society of Public Analysts and Other Analytical Chemists, North of England Section and the Microchemistry Group (joint meeting with the Liverpool and North-Western Section of the Royal Institute of Chemistry, at the Town Hall, Southport), at 2.30 p.m.—Symposium on "Training and Education of Microchemists".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturer (with degree or a recognized diploma in mining) in the Department of Mining and Geology—The Principal, Wigan and District Mining and Technical College, Wigan (September 28).

Research Fellow (with qualifications that are basically physicochemical and/or biochemical, with preferably a leaning towards biological problems) in the Departments of Dermatology and Biomolecular Structure, to carry out fundamental investigations on the structure of the skin in health and disease—The Registrar, The University, Leeds 2 (September 28).

Research Assistant in the Department of Biochemistry for work of a physico-chemical nature—The Secretary, University College, Gower Street, London, W.C.1 (September 30).

Senior Research Officer or Research Officer (with honours degree, with botany as a major subject) in the Commonwealth Scientific and Industrial Research Organization, Division of Plant Industry, to undertake detailed botanical studies of introduced plants which have shown promise in Australia—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2 (September 30).

Guide Lecturer (with degree or equivalent qualification in science or engineering) at the Science Museum—The Civil Service Commission, Scientific Branch, Seventh Floor, Trinidad House, Old Burlington Street, London, W.1, quoting S.4248/53 (October 1).

Lecturer or Assistant Lecturer in Pharmacology at the University College of the West Indies—The Secretary, University of London Senate Committee on Higher Education in the Colonies, Malet Street, London, W.C.1 (October 1).

Research Assistant in Metallurgy to carry out work on the mechanical testing of metals—The Registrar, The University, Manchester 13 (October 1).

Staff-Tutor (with high academic qualifications, preferably in science or art)—The Director of Extra-Mural Studies, 91 Oakfield Avenue, Glasgow, W.2 (October 2).

Engineer (with H.S.C. (science) or equivalent but degree or H.N.C. may be an advantage) at the Ministry of Supply Tropical Testing Establishment, Port Harcourt, Nigeria, to assist in study of effects of tropical conditions on Service materials and equipment—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.222/53A (October 3).

Electrical Engineers (preferably with first- or second-class honours degree in engineering) in the Admiralty—The Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.210/53 (October 8).

Senior Assistants (Scientific) for work involving the observation and recording of critical experiments of a long-term nature carried out at the Experimental Husbandry Farms and Experimental Horticulture Stations of the National Agricultural Advisory Service—The Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.4252/53 (October 8).

Assistant Lecturer in Physics—The Registrar, The University, Manchester 13 (October 10).

Lecturer in Clinical Chemistry—The Secretary, The University, Aberdeen (October 15).

Lecturer or Senior Lecturer (with degree in mechanical engineering) in Mechanical Engineering at Canterbury University College, Christchurch, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (October 15).

Principal Scientific Officer (with first- or second-class honours degree, preferably in mathematics, physics or engineering, or equivalent qualifications, and some postgraduate research experience) in the Department of Scientific and Industrial Research, Mechanical Engineering Research Laboratory, East Kilbride, Glasgow, to lead a team engaged on the thermodynamic tables programme of the Heat Division and the numerical analysis and correlation of experimental data relating to functions of two variables—The Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.4247/53 (October 20).

Principal (with high qualifications, and responsible experience either in the field of technical education or administration, or in industry; preferably in both) of the College of Technology, Bristol—The Chief Education Officer, Council House, College Green, Bristol 1 (October 24).

Assistant Director (graduate in engineering, physics, chemistry or microbiology, and experience of research in the preservation processing and transport of food, preferably fish)—The Secretary, Fishing Industry Research Institute, P.O. Box 1233, Cape Town, South Africa (November 16).

Chair of Botany, and Chair of Geology—The Secretary, Queen's University, Belfast (November 20).

Lecturer in Physiology at the University of Otago, Dunedin, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (November 30).

Chemist, Senior Scientific Officer or Scientific Officer grade (with good honours degree and appropriate research experience), for research on problems of metabolism in the dairy cow and on the composition and digestibility of feeding-stuffs—The Secretary, National Institute for Research in Dairying, Shinfield, Reading, Berks, quoting 53/15.

Entomologist (with good honours degree in zoology or agricultural zoology, and at least two years postgraduate experience or training in entomology) in the Department of Agriculture, Trinidad, for investigation of plant damage by insects and other animals and formulation and application of control measures; also plant quarantine work—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting CSO.53/38/01.

Lecturer (graduate in Agricultural Chemistry or Biochemistry) in Agricultural Chemistry—The Registrar, The University, Nottingham.

Lecturer in Pig Husbandry in the Dairy Husbandry Department—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1, or The Registrar, Massey Agricultural College, Palmerston North, New Zealand.

Lecturer or Assistant Lecturer in the Department of Electronics—The Secretary and Registrar, The University, Southampton.

Physical Chemist for research work on flour quality—Director, Research Association of British Flour Millers, Cereals Research Station, Old London Road, St. Albans.

Research Assistant (with degree in agriculture and practical experience of pig production) in the Pig Research Department, for recording basic experimental data and assisting with research—The Registrar, Wye College, Ashford, Kent.

Senior Geographer (with good honours degree in geography with surveying at an advanced standard and preferably with physical geography or geomorphology as a subsidiary subject, and with several years practical experience or postgraduate research) in the Department of Soil and Land Use Survey, Gold Coast, to carry out topographical survey work in connexion with soil surveys, soil conservation schemes and irrigation projects; to train locally recruited junior officers and to assist in the interpretation of and produce approximate maps from aerial photographs—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting CDE.79/13/04.

Senior Lecturer (with degree, preferably higher, in either agricultural, veterinary or pure science) in Physiology of the Sheep, in the Sheep Husbandry and Wool Department, to lecture on the physiology of growth and reproduction in the sheep and the nutrition of sheep—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1, or The Registrar, Massey Agricultural College, Palmerston North, New Zealand.

Senior Scientific Officer or Scientific Officer (with university degree or equivalent qualification and preferably with experience in ergonomic techniques) for research on the responses of human operators controlling steelworks plant, with special reference to the design and layout of control points in order to reduce fatigue and improve speed and efficiency of operators—Personnel Officer, British Iron and Steel Research Association, 11 Park Lane, London, W.1.

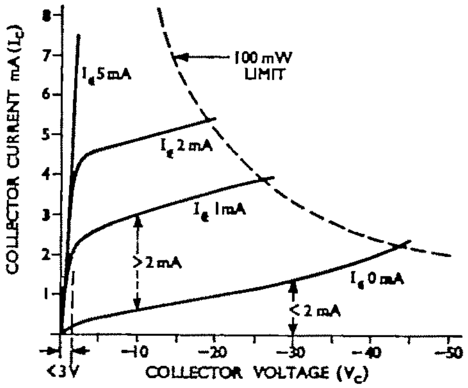
G.E.C.

Germanium Triode GET 1

POINT CONTACT TYPE

now available
to all electronic
equipment
manufacturers



Many progressive designers have made full use of the range of G.E.C. germanium diodes to save power consumption and space.

Now the release of the GET 1 — a germanium triode (transistor) of the point contact type — will enable more designers to reap the benefits of this important development in radio and electronic engineering, where the potentialities of the GET 1 are manifold.

For further information write to
Osram Valve and Electronics Dept.,

RATING

V_c (collector voltage) for short-circuit stability at $V_e = 0$*	−30	max.	V
V_c (DC)	−50	max.	V
I_c (collector current) DC	15	max.	mA
T_{op} (operating temperature)	35	max.	°C
p_c (collector dissipation)	100	max.	mW

Subject to p_c max. not being exceeded.

*V_e = emitter voltage.

CHARACTERISTICS

I_c {at $V_c = -30$; I_e (emitter current) $= 0$}	2 1	max. average	mA mA
V (at $I_c = 2$ mA)	3 1.5	max. average	V V
I gain {at $V_c = -10$; I_e range 0–1 mA}	2 2.5	min. average	

GENERAL The GET 1 is hermetically sealed in a metal can, which is insulated from the electrodes. The can may be earthed when necessary.

THE GENERAL ELECTRIC CO. LTD., MAGNET HOUSE, KINGSWAY, W.C.2

WATCHMAKERS' EYEGLASSES

This popular magnifier is widely used outside the watchmaking trade. The mount is of non-inflammable black polished plastic which is nearly unbreakable; it is fitted with a Bi-Convex Lens having a standard focus of 3in. (75mm.), giving a magnification of 3½ times.

Ready late October

EXERCISES IN THEORETICAL STATISTICS
M. G. KENDALL
Professor of Statistics, University of London

Good exercises in theoretical statistics are not easy to come by, and it is with pleasure that teachers and students of statistics will welcome Professor Kendall's new book. The exercises concentrate on basic theory and come under five main groups: distribution theory, sampling theory, relationship, estimation and inference, and time series. The book will be of special use to students who are studying privately, as answers and hints on solutions have been added.

Pp. viii+180 (8½ in. × 5½ in.) Price approx. 20s.

Fifth Edition

RICHMOND'S DAIRY CHEMISTRY
revised and enlarged by
J. G. DAVIS, D.Sc., Ph.D., F.R.I.C.
F. J. MACDONALD, A.R.I.C.

Dairy and food chemists everywhere will welcome this new and enlarged edition of 'Richmond' because they know it as a book that has long been indispensable. It brings together the essential information on the chemistry of milk and dairy products and the relevant analytical methods, and with this revision it becomes fully up-to-date. The material of permanent value in previous revisions has been retained, and there has been added, apart from other material, information giving the results of ten years' research on the construction, chemical and physical properties, and examination of dairy products.

Pp. viii+603 (9 in. × 6 in.) Price 60s. net

CONTROL OF UNIVERSITY EXPENDITURE

In a memorandum of May 28, 1952, the Treasury rejected the recommendation made by the Select Committee on Estimates in its fifth report for the Session 1951–52 that the Comptroller and Auditor General should have the right to inspect the books and accounts of universities in Great Britain so far as these relate to money advanced by means of non-recurrent grants for capital development. The Treasury pointed out that the Committee of Public Accounts is also concerned to see that all the funds of a grant-aided body are subject to the scrutiny of the Comptroller and Auditor General, and does not select one particular sort of grant for this treatment. The criticism was not construed, however, as suggesting that non-recurrent grants to universities could be treated separately from recurrent grants. The memorandum reiterated the view that Treasury control over non-recurrent as well as recurrent grants should be exercised on broad lines, and that questions of detail should be left to the University Grants Committee. The Treasury was satisfied that the latter Committee, with the assistance of its Works and Building Sub-Committee and of the Ministry of Works, scrutinizes critically the plans of new buildings for which grant aid is sought; that the universities are required to put grant-aided work out to tender, and to accept the lowest tender unless they can satisfy the University Grants Committee that there is good reason to the contrary; and that schedules of equipment for new buildings receive expert scrutiny from the appropriate sub-committee of the University Grants Committee. Furthermore, the Treasury emphasized its view that while the books and accounts of any new bodies receiving public grants should be subject to inspection by the Comptroller and Auditor General, the introduction of such procedure might create difficulty with some old-established institutions, such as the universities, which had been receiving grant-in-aid for many years.

It would seem that both the Select Committee on Estimates and the Committee of Public Accounts have accepted the view of the Treasury so far as recurrent grants are concerned; but in its third report for the Session 1952–53 (No. 203; pp. 38; London: H.M.S.O.; 1*s.* 3*d.* net), the Committee of Public Accounts again presses the view that the present system of controlling non-recurrent capital grants falls short of what Parliament is entitled, or accustomed, to expect; and urges that in future the books and accounts of the universities relating to expenditure of grants for non-recurrent purposes should be open to inspection by the Comptroller and Auditor General. It agrees that the autonomy of the universities must be preserved, but is unconvinced that their independence would be prejudiced by the step proposed.

In a Minute of November 18, 1952, in which the Treasury stated that it is difficult to see what purpose the proposed inspection could serve which is not already covered by the existing audit of university accounts, it was also remarked that the question whether due economy had been exercised inevitably raised questions of academic policy, and for this reason the Treasury had hitherto taken the view that its control over non-recurrent as well as of recurrent grant should be exercised on broad lines and that questions of detail should be left to the University Grants Committee. It also appeared from this Minute that the University Grants Committee has itself disallowed in assessing grants certain costs incurred by the universities.

The Committee of Public Accounts takes the surprising view that such action by the University Grants Committee supports its own argument for independent inspection of accounts, though it could equally be taken as evidence that the Treasury point of view is right and that inspection would serve no purpose. No fresh evidence in favour of such an opinion is advanced by the Committee, although, apparently on the sole ground that the Treasury was unaware what instructions were issued to the auditors of the universities' accounts, the Committee held that it could not give Parliament an unqualified assurance that there is no irregularity or abuse, and that the grants have been spent on the purposes for which they were voted, with due regard to the elimination of waste and extravagance. "Such assurance in their opinion can best be given through the Comptroller and Auditor General, whose approach to these matters is different from that of the professional auditor." The term 'best' is used, but it would seem that 'only' is meant. The argument is thin and unconvincing; but the report is disturbing, less because its lack of perspicacity reflects on the ability and outlook of the Committee itself, than because the Committee itself is to some extent a microcosm of the House of Commons. The proposal to upset the present admirable but delicately balanced financial relationship between Government and the universities of Great Britain will doubtless be once again firmly rejected, as it should be. That it should still be advanced by a representative committee of the House of Commons, even if that committee is charged with the responsibility of watching the public purse, suggests that there is lack of clear understanding, on one hand, of the work and functions of the universities, and, on the other, of the limitations and comparative functions of executive and representative bodies.

Under its terms of reference, the University Grants Committee is responsible for advising the Government on the administration of Parliamentary grants in aid of the universities, and Parliament, on those sound principles so clearly defined by J. S. Mill, has refrained from all attempts to supervise the spending of this money in detail. It has entrusted that responsibility to a group of men with close knowledge of the universities and of the academic standing that commands the confidence both of the Government and of the universities themselves. These men possess the knowledge enabling them to determine in detail the proper objects of academic expenditure, the effect of particular proposals on the balance of studies, of teaching and of research. If they are found not to possess the integrity to use that knowledge wisely, then the elimination of waste and extravagance, of irregularity or abuse, will not be secured by interference from those who do not possess such knowledge: the remedy lies in replacing them by others who possess both the knowledge and the integrity. There is, of course, no suggestion in this or in earlier reports of any lack of confidence in the integrity of either past or present members of the University Grants Committee. The trouble is probably rooted rather in over-confidence in the omniscience of either a Minister or a government official. On matters of broad policy, the Government may, and does, give some guidance to the University Grants Committee, as, for example, in regard to the nation's requirements for particular types of academically trained men and women; a Government Department can indicate some specific or broad fields in which new knowledge is desirable, but wisely the arrangements by which such ends should be achieved are left to the Committee and the universities themselves.

The report is disturbing for the indication it affords that there is some lack of public understanding of the position of the universities in Great Britain, of the way they function, and their true relations to the Government. Without that understanding, such a system as the University Grants Committee will manifestly become unworkable, and all the sooner in view of the demand for closer accountability which the growing dependence of the universities on public support is likely to engender. The ill-judged recommendation from the present Committee of Public Accounts and its support from the Select Committee on Estimates may in part be due to the lack of experience, on which Mr. Basil Chubb laid such stress in his study of the control of public expenditure, or to the increasing difficulty, in view of existing demands on Parliamentary time, of finding members with the requisite ability, judgment and experience to serve on such committees. It certainly reflects lack of public understanding of the functions and purpose of the universities on the part of those who are elected to Parliament.

The last quinquennial survey of the University Grants Committee and the subsequent discussion at Cambridge during the Congress of Universities of the Commonwealth are well calculated to increase such public understanding. It might be emphasized that such reports are the material to which any such bodies as the Estimates and the Public Accounts Committees should turn in the first instance as a basis for forming a sound judgment as to the wise expenditure of public funds by the universities. Accounts are only one method—and that not the first method—of determining whether the nation is getting full value for its expenditure of some £20 millions and more. As Sir Frank Tribe told the members of the Institute of Public Administration, no examination based on figures alone can lead to a proper judgment on the efficiency of a concern or a Department of State.

The tentative suggestions which Sir Frank Tribe made in that lecture four years ago for criteria and possible bases of comparison warrant further careful study; but their value, whether in regard to the grant-in-aid of universities or in regard to national expenditure in general, is likely to be assessed more accurately by expert administrators than by a Select Committee. What is even more disturbing than the lack of understanding of the functions of the universities is the evidence that Parliament fails to grasp the essential limitations and the true function of a representative body as against the executive. "The proper duty of a representative assembly in regard to matters of administration," wrote Mill, "is to take care that the persons who have to decide them shall be the proper persons." It is only when this limitation is kept in mind that a Select Committee can perform usefully and efficiently that vital function of a public watch-dog, putting the light of publicity on the acts of Government Departments and compelling a full exposition and justification of anything which appears questionable, and censuring fearlessly where required. That function, however, will not be performed effectively unless both the Committee and the House understand clearly the limits within which it can be exercised: criticism, and even censure, lose much of their force and weight if the body making them has lost credit and reputation by making representations on matters in which it manifestly has not, and could not be expected to possess, the requisite depth of knowledge. Similarly, the effective control of public expenditure demands on the part of Parliament a readiness to accept and to act on responsible and independent criticism, and not to impute political prejudice even when findings are, as has already happened and will doubtless happen again, counter to the doctrines of a political party.

It may be taken for granted that, in view of Mr. Butler's remarks to the Congress of Universities of the British Commonwealth on July 14 regarding academic freedom, the Government is unlikely to accept any recommendation which will threaten that freedom or disturb the existing mutual confidence between Parliament and the executive and the universities. Moreover, the chairman of the Committee of Public Accounts, Mr. G. Benson, has now explained, in a letter in *The Times*, that the proposal is not that the Government, much less the Comptroller and Auditor General, should "determine in detail the proper objects of scholarly expenditure". The proposal, he now explains, is simply that the Comptroller and Auditor General should examine the methods of contracting and of recording and controlling expenditure in order to judge whether these are reasonably designed and properly applied to ensure effective safeguards against waste and extravagance or other abuse. The proposed examination would be directed to the broad question whether the financial arrangements are likely to provide the building required by the policy-makers without waste or extravagance.

This disclaimer of any concern with academic policy puts a different complexion on the proposal. It could not be gathered from the report itself that no more was intended than a review of the methods used to secure effective control of the cost of building works, an objective notoriously difficult to achieve, as Mr. Benson rightly points out. This experience suggests that review by the Public Accounts Committee of such expenditure has enabled the Ministry of Works to strengthen its own control over its building expenditure, and thus has led to increased economy. This explanation should have found a place in the report itself. If, as it stands, the report does some undeserved harm to the reputation of the Committee, real good may have been done by this further demonstration of the need for more public understanding of the work of the universities and of the mechanism of public control and the functions of a representative body. It cannot be too clearly stated to-day, with the increasing rigidity of control over the individual member which a close balance between political parties almost inevitably entails, that Parliamentary control, whether over expenditure or policy, cannot be either wise or effective if members sacrifice their judgment to the majority opinion. To-day, as in Burke's time, the integrity and vitality of democratic institutions depend ultimately on the extent to which members of Parliament, and like assemblies, in the full House or on its committees, preserve and act on their own unbiased opinion, their mature judgment and their enlightened conscience.

SCIENCE AND FAITH

Modern Science and Modern Man

By James B. Conant. (Bampton Lectures in America No. 5, delivered at Columbia University.) Pp. iv+111. (New York: Columbia University Press; London: Oxford University Press, 1952.) 14*s*. 6*d*. net.

Science and Faith To-day

By John Baillie, Robert Boyd, Donald Mackay and Douglas Spanner. Pp. 60. (London: Lutterworth Press, 1953.) 3*s*. net.

In four essays on science and technology in the past decade, the changing scientific scene, 1900–50, science and human conduct, science and spiritual values, which constitute this book, Dr. J. B. Conant ranges over a wide field but is never superficial. His essays attempt to provide some interpretation of the significance for the whole social pattern of Western civilization of developments in physical science during the past twenty years, and including the effect of the impact of modern science on the philosophical presuppositions of the average enlightened citizen of a modern democracy. They are addressed, not so much to the professional philosopher or scientist, as to the educated citizen, whether graduate or not, and should be appreciated as much in Great Britain as by the audience at Columbia University to which, as the Bampton Lectures, they were first delivered last year.

Dr. Conant suggests first that the changed status of the scientist is one of the major significant features of the past decade. The scientist is no longer thought of as a man in an 'ivory tower' but as a miracle-worker who can bring about tremendous transformations of man's relations to his material surroundings. The scientist has displaced the inventor in the mind of the general public as the prime mover of technology, and thus has arisen the current fallacy which tends to equate the scientist with a magician. Dr. Conant recognizes the danger of this fallacy; but he does not suggest that it is serious enough to offer any real threat to the advance of science. He is much more concerned about another major development—the changed relation of many scientists to organized society, that is, the government, and the effect of secrecy. Those who are competent to discuss the future of atomic energy, he points out, cannot do so because of security regulations: it is impossible to-day or in the foreseeable future to have a frank, rational, searching discussion of the industrial uses of atomic energy. Secrecy and science are fundamentally antithetic propositions.

It is important that the general public should understand the consequences of the union of secrecy and applied nuclear physics; but Dr. Conant accepts that union as inevitable for a long time to come. At the same time, he admits the risk that so large a proportion of scientific resources may be devoted to work in this field that the traditions that have made science possible will be threatened. Really significant advance has come not from empiricism but from new theories, and the essential element in the advance of modern science has been a diminishing degree of empiricism and the increase of theory.

Dr. Conant is content to point in passing to the danger to the advance of science which such conditions represent and to insist on the importance of the public being aware of the danger. He is much more concerned with the changed attitude of the public towards science and the altered viewpoint of the scientist towards science which is the theme of his second lecture; but, in suggesting that we are concerned with a break in the continuity of a line of argument and in challenging the claim that science is teaching us more about the nature of physical reality, Dr. Conant enters on debatable ground. Indeed, his scepticism seems inconsistent with his previous claim that the advance of science is marked by a diminishing degree of empiricism.

It is true, as he points out, that the failure to settle by experiment the validity of the wave theory versus the corpuscular theory of light has been a prime factor in changing the scientific point of view, and Dr. Conant defines science as "a series of interconnected concepts and conceptual schemes arising from experiment and observation and fruitful of further experiments and observations". This definition leads him to suggest that the test of a scientific theory is its fruitfulness, or its ability, in J. J. Thomson's words, "to suggest, stimulate and direct experiment". A scientific theory, he argues, is not even the first approximation to a map; it is not a creed but a policy—an economical and fruitful guide to action by scientific investigators.

Dr. Conant does not make his distinction quite clear. A scientific theory is admittedly not a creed, and it may be useful to regard scientific theories as guides to human action and thus an extension of common sense. Dr. Conant, in fact, stresses the way in which the results of scientific activity have become intermeshed with common-sense ideas when, later, he points out that scientific concepts are so much a part of the equipment of men and women in our culture that they are used both consciously and unconsciously in making decisions that we call ethical or moral. But both a map and a policy must be credible if a consistent course is to be set or a firm policy pursued, and Dr. Conant seems to overlook the sizable act of faith that is involved, no matter how ready we may be to discard a theory. Nor is it easy to believe that scientific work would be pursued with quite the same ardour if it were as divorced from reality as Dr. Conant implies, and if the investigator did not believe he was gaining some insight into the nature of the physical world.

The importance of this point is perhaps brought out more clearly in a little book, "Science and Faith To-day", which covers much of the ground that Dr. Conant covers and has more in common with his book than might appear at first sight. Dr. John Baillie, in the first of the five chapters of this book, which constitutes a shortened version of an address he gave to the British Association at Edinburgh in 1951, insists quite as strongly as Dr. Conant that we are concerned with two diverse ways in which the whole territory of our human experience may be approached and explored (using the simile which Dr. Conant rejects). Like Dr. Conant, he recognizes how largely our general outlook on life has been affected by the scientific approach to things. As Dr. Conant admits, regarded as guides to human conduct, common-sense ideas and scientific concepts interpenetrate to such an extent that no one can say where one begins and the other ends, and any attempt to draw a sharp line between common-sense ideas and scientific concepts is not only impossible but even unwise.

Dr. Conant rightly adds that the notion that the scientist is a cool, impartial, detached individual is absurd and to be rejected, and that this interpenetration means that even in his laboratory the scientist cannot escape making judgments of value. It is not enough, however, to make the point that the antithesis between science and value-judgments is false and to ignore the nature of scientific undertakings and the motivation of many scientists. Unless, as Dr. Baillie points out, the conduct of affairs is determined by some belief in moral and spiritual values, even science itself is threatened. The irresponsible exercise of power is fatal to the continuance of science as of civilization; and the responsible exercise of power is an act of faith.

Dr. Conant does, it is true, in his last lecture face this problem of spiritual values. He admits that the scientific investigator has to believe as well as to doubt and question, and that, in regard to many phenomena, as men of action we require at least provisional beliefs. Nor does he suggest that the benefits that flow from scientific investigations are all material. He believes that science creates an atmosphere encouraging to those who believe that man is not merely a social animal: the history of the past three centuries is a record of the flowering of the creative powers of the human mind as well as of achievement in the manipulation of ideals, and the lectures close on a note of humility.

Nevertheless, Dr. Conant's book seems to need the message which Dr. Baillie, Dr. Robert Boyd, Dr. D. Mackay and Dr. D. Spanner convey in their broadcast talks to complete his interpretation. Dr. Boyd, for example, puts even more clearly the point that our value-judgments are, and must be, made as complete men, not just in our capacity as scientists. Dr. Mackay, who likewise emphasizes the personal character of religious experience, clears away some of the confusion which Dr. Conant's analysis has left with his distinction between the language of the actor and the language of the observer, and his warning against using words or concepts defined for different logical backgrounds; the fact that Dr. Spanner's approach to the limitation of science is from a direction entirely different from Dr. Conant's helps to throw a fresh light on this question of the relation between science and what Dr. Conant terms spiritual values.

Dr. Conant himself appears to recognize as clearly as Dr. Baillie and his fellow-writers that we are concerned not with two separable regions of experience but with two complementary aspects of it. He would seem to agree again with Dr. Baillie that the supreme values or certainties in music and in literature, for example, are those which science can do nothing either to suggest or to establish. He appears to agree also that by exposing the manner of Nature's operations science enables us to harness those operations to attain ends which we spiritually discern to be worth while, and that scientific knowledge is worth having for its own sake even when it leads to no practical result; but he seems more sceptical as to the third service which Dr. Baillie claims that science renders: it helps to provide an element of otherness and conflict which is a necessary part of our spiritual discipline.

Dr. Conant himself recognizes the variety of human experience and goes far to meet Dr. Baillie's point when he concedes that the scientist himself has to exercise faith as well as to probe and criticize. The whole spirit of this little book on science and faith, with its insistence that science and faith are complementary conceptions or aspects of a life which has to be lived as a whole, and its refusal to accept limitations on scientific inquiry or to stifle faith, gives a new meaning and direction to the traditional conflict between science and faith. They are seen rather as two complementary elements in the ceaseless search for truth, and these essays, which cover so much ground common to Dr. Conant's book, seem well designed to complete an explanation and interpretation of the place of science in the modern world which Dr. Conant attempted but just failed to unfold completely and satisfyingly. R. BRIGHTMAN

DEVELOPMENTS IN PHYSICS

Reports on Progress in Physics

Vol. 15 (1952). Executive Editor: A. C. Stickland. Pp. iv+338. (London: Physical Society, 1952.) 50s. net; to Fellows, 27s. 6d. net.

SINCE its introduction in 1934, fifteen volumes of the "Reports on Progress in Physics" have appeared, and a wide variety of individual subjects have been reviewed, some several times, as the cumulative author and subject indexes for Vols. 1–15, appended to Vol. 15, illustrate. Although the "Reports" seem to be getting more and more specialized each year—perhaps too specialized—no physicist who wishes to keep up to date with advances in the many rapidly developing fields of physics can really afford not to peruse these volumes.

Vol. 15 contains nine articles of varying length and merit, and the subjects treated, in which both theoretical and technological aspects are represented, cover a wide field. The longest, some seventy pages, and undoubtedly the best article in the volume, is by G. V. Raynor and is concerned with the band structure of metals. It is significant that although there are several recent monographs on this particular subject, the author has no need to refer the reader to them, except when some specific aspect, such as the behaviour of semiconductors or ferromagnetism, is deliberately omitted from consideration. In the introductory section the major advances in the development of the electronic theory of metals since the early Lorentz theory are rapidly, but very skilfully, recapitulated, and then the major part of the remainder of the report is devoted to a review of the electronic structures of typical classes of metals. The mathematical complexity of the subject is carefully avoided, without any loss of clarity, and no physicist need be afraid that through lack of familiarity with the subject he will be unable to follow Raynor's exposition. The research worker, too, will be pleased to read that, though qualitatively the nature of metallic substances is now clear and in many cases there is good agreement between experiment and theory, considerable gaps, which are all carefully detailed and explained by Raynor, exist and are well worthy of his attention.

Turbulent motion in fluids is treated in a forty-page article by G. K. Batchelor and is the third on the subject to appear in the "Reports". It is sixteen years, however, since the last report, and in that time the literature on turbulent motion has more than doubled. In addition, much progress has been made in the clarification of the essential physical nature of the problem and in the recognition of the almost ubiquitous presence and importance of turbulence in physical problems. Nevertheless, the phenomenon of turbulence is still much of a mystery, and, to quote Dr. Batchelor, what has been achieved is that "we can state what we do not know more closely than we could sixteen years ago". The main article is followed by a short appendix in which the principal advances in measuring technique, particularly of the hot-wire anemometer, is summarized by A. A. Townsend.

Nuclear physics is represented by two articles. Range–energy relations are discussed by A. E. Taylor, of the Atomic Energy Research Establishment, Harwell, and high-energy neutron–proton and proton–proton scattering data are analysed by R. S. Christian, formerly of the Los Alamos Scientific Laboratory, New Mexico. These two articles obviously are not of general appeal; but the mass of experimental information which has been accumulated by using charged particles accelerated to high energies of 300 MeV. or more, or heavily charged particles in the form of fission fragments, is important and may give a lead to a more comprehensive and satisfactory understanding of nuclear forces than exists at present.

A report by A. Fairweather, F. F. Roberts and A. J. E. Welch, of the Post Office Research Station, is devoted to a description of the preparation and the physical and chemical structure of ferrites and to a brief outline of Néel's theory of ferrimagnetism. Ferrites first attracted engineering interest as non-metallic ferromagnetic materials for use at frequencies where, in the more usual metallic materials, eddy currents have undesirable effects, but they are now studied mainly in order to obtain a deeper understanding of the ferromagnetic and anti-ferromagnetic behaviours of non-metallic substances. The literature on ferromagnetism and anti-ferromagnetism is extensive, but the subject-matter is not easy to follow, and it is unlikely, in spite of the brave attempt made by the authors of "Ferrites", that any but those who already have a good grasp of the subject will benefit from reading this report.

The survey given by L. Kellner of the infra-red spectra of substances capable of forming a hydrogen bond, and of the hydrogen bond postulate, is another highly specialized, though quite brief, report. This is followed by a useful description, by K. I. Mayne, of recent theoretical work on the improvement in design of spectrometers and of their application, with enhanced sensitivity, in geological and biological problems and in nuclear chemistry.

In the remaining two articles electrical phenomena are dealt with. The galvanomagnetic effects (the Hall field and magneto-resistance) in conductors are fairly well reviewed by D. K. C. MacDonald and K. Sarginson, but the report might have been improved by the expansion of the first part, the physical survey, with appropriate brief references to the theoretical problems and by omission of the second part, the mathematical treatment. Finally, there is a most interesting, but somewhat verbose and loosely written, account of travelling-wave tubes by R. Kompfner. These tubes are of importance in microwave electronics and have recently found application in communication engineering. Since the Second World War much of the progress is due to J. R. Pierce, of the Bell Telephone Laboratories, though Kompfner himself has made important contributions, and several novel types of tubes have been evolved. The fundamental principle of operation is understood, and much theoretical work has been carried out; but not all the problems have been solved, and experimental work still lags behind theory. The result of Kompfner's survey can therefore be summed up in his own words—namely, that it is impossible, at this stage, to assess the degree of importance which is to be attributed to the various discoveries, devices and developments and to put them in their proper perspective. It may be asked, therefore, whether this is the proper time for such a progress report.

TREATISE OF PALÆONTOLOGY

Traité de paléontologie

Publié sous la direction de Prof. Jean Piveteau. Tome 1: Les stades inférieurs d'organisation du règne animal; introduction, par J. Piveteau; généralités, par J. Roger, H. Tintant, C. Dechaseaux, L. Cuénot and A. Tétry; Protistes, par G. Deflandre, A. Sigal et R. Ciry; Spongiaires, par L. Moret; Cœlentérés, par J. Alloiteau et M. Lecompte; Bryozoaires, par E. Buge. Pp. vii+782+10 plates. 8900 francs. Tome 2: Problèmes d'adaptation et de phylogenèse; Brachiopodes, Chétognathes, par J. Roger; Annélides, par C. Dechaseaux et J. Roger; Amphineures, Scaphopodes, Lamellibranches, par C. Dechaseaux et G. Lucas; Gastéropodes, par H. et G. Termier; Céphalopodes, par E. Basse, G. Delépine et J. Roger. Pp. vii+790+24 plates. 9700 francs. (Paris: Masson et Cie, 1952.)

THE first two volumes of Prof. J. Piveteau's seven-volume "Traité de paléontologie" bear witness to the enormous increase in range and complexity of the subject since the last edition of the classic work of Zittel. Six volumes are now needed to cover the animal kingdom excluding man, to whom one volume is to be devoted, and in many Classes the proportion of genera listed to genera recognized is much smaller than in the older work.

Co-operation between editor and printer has resulted in the successful execution of a well-planned lay-out. In the systematic parts, family and subfamily headings in sans serif could have been made more conspicuous by insetting. The latter are particularly difficult to see. Footnotes in these sections (fortunately few in number) are also insufficiently differentiated. In all other respects the book is well produced and easy to work with, though more use might have been made of right-hand page-headings. Illustration, especially of morphological features, is abundant and the photographs of specimens give a more direct idea of the fossils than any line-drawings could convey. The post-Palæozoic corals and the ammonites are even illustrated by collotype plates—the latter quoted from F. Roman's "Les Ammonites Jurassiques et Crétacés" (1938).

Space forbids review of individual chapters, but many general points invite criticism. From Prof. Piveteau's introduction it would appear that nothing significant in palæontology has ever been done outside France (with one Belgian exception). This attitude has fortunately not affected the contributors. The chapters on general principles display that characteristically French blend of authority with enthusiasm which disarms criticism. The various topics are incompletely covered, but the freshness and vigour of the writing should inspire students to understand more about the science and to fill in the gaps by further reading. Unevenness in quality and inconsistency in detail impair the potential utility of the work. Editorial policy could have assured consistency in, for example, citation of author and date for the various systematic categories; statement of scale of magnification or reduction of figures; indication of type-species when cited (too often species are omitted altogether); and adherence to the International Rules of Zoological Nomenclature, especially as regards the use of pre-Linnean names (for example, Vol. 1, p. 666).

The introduction of new zoological names in works of reference is generally condemned; such names are easily overlooked, and there is seldom space for adequate description and discussion. Of several cases in the "Traité" perhaps the worst is on p. 593 of Vol. 1, where a new genus and species are proposed without systematic context. This new genus is not mentioned in the systematic catalogue or in the index. New family names are perhaps less objectionable in text-books, but new names at higher levels involve major taxonomic problems as well as the ethics of teaching. Students have a right to expect that the classifications presented in text-books shall claim at least a large measure of acceptance among competent authorities. A new classification of the post-Palæozoic Corals is here put forward with a persuasiveness and a wealth of illustration which command admiration, but it is doubtful whether there has been the opportunity which is desirable for criticism by interested specialists.

The chapter on the Flagellata epitomizes more than twenty years of pioneer research by M. and Mme. G. Deflandre and merits special welcome. That on the Foraminifera also displays outstanding ability. Of the remaining chapters, the majority are adequate to their purpose, but the systematic parts of those on the Lamellibranchia and Gastropoda have been too drastically shortened and the space allotted to the Rudistidæ in the former is disproportionately large.

As works of reference, these two volumes will be found more valuable on general questions than as taxonomic handbooks. The best things have the true Gallic brilliance and penetration and will endure. The weaker parts show that so formidable a task as this is not to be lightly undertaken. It is to be regretted that the books are priced beyond the reach of students.

R. V. Melville

PREVENTIVE MEDICINE ON THE FARM

At the Liverpool meeting of the British Association, Section M (Agriculture) devoted the morning of September 7 to a discussion on "Preventive Medicine among Farm Livestock" with Dr. John Hammond (Cambridge) in the chair. The prominence of animal health in the programme of this section illustrated both the close association between agriculture and veterinary science and the need for increasing animal production.

In his introductory remarks, Prof. E. G. White (University of Liverpool) defined preventive medicine as "keeping animals healthy by preventing disease" and illustrated some of the ways in which farm livestock can be protected against diseases, whether introduced at intervals from abroad (foot-and-mouth disease, anthrax, fowl pest) or established within Great Britain. Prevention, said Prof. White, is not only better than cure, it is also cheaper, which is an important advantage to the farmer.

A number of serious animal plagues were eradicated from Great Britain by restriction of the importation of animals and raw animal products, slaughter of affected animals and in-contacts, and sanitary measures. These methods are still used for some of the diseases that enter Britain from time to time, such as the serious and widespread outbreaks of foot-and-mouth disease during 1951–52 which were due to infection from Europe, possibly transmitted by migrating birds. In recent years two more notifiable diseases, parasitic mange of horses and sheep scab, have been eradicated. Protection of stock with vaccines and other biological agents is of particular value where the causal agents of disease live in the soil, as with a number of sheep diseases. Vaccination is also of great value for contagious abortion in cattle and swine fever. With internal parasites, such as liver flukes and nematodes, it may be impossible entirely to prevent animals becoming infected. The method of control is to limit the level of infestation by proper grazing practice, to control disease by strategic dosing with anthelmintics and to provide a good standard of nutrition in order to increase the host's resistance to the parasites.

Poisoning among farm animals, particularly lead poisoning in cattle caused by licking painted wood or metal objects, can usually be prevented. Fluorosis has been found to be a serious problem in the neighbourhood of certain types of industrial plant: brick works, aluminium works and some types of steel works have been incriminated. Piped main water is a valuable weapon of preventive medicine on the farm; too many farms still have to rely on wells and ponds for their water supply. This makes clean milk production and disinfection difficult, and favours the spread of disease.

The losses due to disease in livestock are difficult to assess because there are no accurate figures for disease incidence, except for the notifiable diseases. Losses certainly amount to many millions of pounds each year. Much of this loss can be avoided. Damage to hides due to the larvæ of the warble fly, for example, caused a loss of nearly half a million pounds to the Ministry of Food in 1952: the fly could be eradicated from many areas if cattle were regularly dressed with the statutory preparations.

The disease picture is continually changing. When new methods of control become effective against some diseases, others are brought to light. Thus control of trichomoniasis revealed *Vibrio fœtus* as a cause of infertility in cattle. The use of antibiotics for mastitis, vaccination for contagious abortion and several sheep diseases, and anthelmintics and insecticides for internal parasites has greatly reduced the losses from these diseases in recent years, and more attention can now be paid to the diseases that remain. Preventive medicine embraces not only those diseases that are caused by infective agents but also covers a much wider field, including the prevention of nutritional and metabolic diseases and poisoning and the avoidance of methods of breeding, housing or management that favour disease. With better control of infectious diseases there is an opportunity to devote more attention to diseases caused by factors other than infective agents.

Prof. White concluded by remarking that although the cure of existing disease and the relief of suffering are very necessary, the first duty of medicine is to prevent disease. But whereas the successes of curative medicine are easily measured, the real triumphs of preventive medicine are not, for they are the things that do not happen.

The contribution of the State to disease prevention and control, through the full-time staff of the Animal Health Division and the panel of part-time veterinary practitioners, was dealt with by Mr. J. N. Ritchie (chief veterinary officer, Ministry of Agriculture and Fisheries).

Mr. Ritchie dealt first with the notifiable diseases which owners are required by law to report to the police when they are suspected. Some of these diseases (cattle plague, bovine pleuropneumonia, sheep pox, glanders, epizootic lymphangitis and rabies) have been eradicated by slaughter of affected and in-contact animals, control of importation and movement, and sanitary measures. Modern sheep dips containing 'Gammexane' have helped to eradicate sheep scab because they necessitate only a single dipping instead of double dipping. There has been no sheep scab in Scotland for twelve years and none in England and Wales since 1951.

A wide variety of regulations exist to control the importation of animals, animal products, and goods that may convey infection mechanically from abroad; but since we must still depend to some extent on imported animal feeding-stuffs and fertilizers and on imported meat, a certain amount of risk must be accepted. Outbreaks of anthrax usually arise from imported feeding-stuffs and fertilizers, and during 1952–53 there was a particularly high incidence of the disease, especially among pigs. Three-quarters of all primary outbreaks of foot-and-mouth disease are probably caused by infected swill containing the virus in the form of waste meat from imported chilled carcasses. The separation of swill from livestock until it has been boiled for one hour is a valuable method of preventing this disease, as well as swine fever and fowl pest. Swine fever is perpetuated by movements of pigs through markets and dealers' premises, and its control is fairly rapid when movement restrictions are imposed. Greater use of vaccination would help to reduce the incidence of the disease. Fowl pest was re-introduced into Britain in 1947 with imported poultry carcases, after fourteen years freedom from infection. Control is by the slaughter of infected and in-contact birds but is hampered by the occurrence in recent years of a sub-acute form of the disease which is difficult for the farmer to detect but is very contagious.

Perhaps the greatest achievement of preventive veterinary medicine of recent years is the scheme to eradicate tuberculosis from cattle by the Attested Herds Scheme and the establishment of free-testing, eradication and attested areas. By the end of March 1953 almost four million cattle, representing 41·4 per cent of the total stock, were in attested herds. Attested areas containing some 700,000 cattle have been established in south-west Scotland, south-west Wales, Shetland and the Scilly Isles. Adjacent to the areas in Scotland and Wales are free-testing areas containing another million cattle which will soon more than double the cattle population in attested areas. Abortion due to brucellosis has been well controlled by vaccination, and that due to trichomohiasis has responded to treatment of infected cows and the use of artificial insemination.

In addition to the field-work involved in preventing and controlling disease, the Animal Health Division has a laboratory diagnostic and research service which operates from two main laboratories at Weybridge and Lasswade and from the divisional diagnostic laboratories which exist in most counties and the Veterinary Investigation Centres.

Dr. E. L. Taylor (Weybridge) introduced the subject of parasitic diseases by stating that half of the living creation is parasitic on the other half, and that the species of parasite are more numerous than the species of host on which they live. Dr. Taylor illustrated the importance of parasitic disease on animal production by discussing the losses caused by the parasitic nematodes. He presented a picture of parasitism of stock in four periods in history. In the first period, a mythical Garden of Eden, parasite and sheep lived happily together because there was plenty of room for animals to graze and so the intake of infective stages of the parasites was small. Sheep were able to maintain their worm population at a level which was compatible with health. In the second period, that of trial and error, farmers began to domesticate animals, to enrich the soil and to fence the land. Parasites flourished and losses among farm stock were severe. By a process of trial and error farmers found ways of reducing their losses. There followed the present age, the age of reason, during which knowledge of parasites and their life-histories enables man to use anthelmintics and methods of pasture management which help to reduce losses. An experiment at Weybridge with twin lambs, one of each being kept worm-free and the other infected with a moderate number of worms, showed that by the end of the year the average weight of the infested lambs was some 30 lb. less than that of their worm-free twins. This difference occurred in spite of anthelmintic treatment. Since worms are ubiquitous where sheep are kept, this difference between optimal gain and 'normal' gain is very considerable, and Dr. Taylor calculated that even if the difference amounted to only 10 lb. per lamb it would mean a loss of some 18,000 tons of meat a year.

The fourth age, the age of eradication, has hitherto seemed to be unattainable; but there is now some hope that, at least for some species of worm, it may well be reached. Experiments by Dr. Spedding at the Grassland Research Station with sheep on arable land have shown that the use of phenothiazine, together with a folding system, can enable sheep to be kept free from worms altogether. Although such a procedure may not for a long time become practicable farming practice, it nevertheless marks a beginning, and with the development of better parasiticides may well open up a method which could enable animal production to be raised to a level far higher than had been thought possible.

The symposium ended with a contribution from Mr. J. O. L. King (University of Liverpool) on the influence of animal husbandry on disease. Domesticated livestock of to-day, Mr. King said, are very different from their wild ancestors. Their greatly increased productivity demands high standards of nutrition and management and protection from bad weather. Whereas the importance of nutrition and genetics is well recognized, the influence of environmental factors on disease incidence is not given the attention it deserves. A recent study by Withers of calf losses showed that the increased mortality in the early spring is greatest in the northern half of Britain and is probably due to the adverse effects of extreme cold, wide temperature ranges, and absence of sunshine. Phillips, from a study of knackery records in West Wales, showed a great increase in cows slaughtered during April each year, which is probably a reflexion of the adverse effects of confinement indoors on an inadequate diet during the winter months. Stock require to become acclimatized to colder and more rigorous conditions, which is why farmers prefer to "go north" for stock replacements. Mr. King gave a number of illustrations of the adverse effects of sudden changes of environment on farm stock, particularly in relation to their fertility. Pigs are particularly susceptible to a cold and damp environment, and the cost of providing heat for very young pigs is well repaid by a higher survival-rate and better growth. Cattle can with advantage be given more fresh air and exercise than the conventional cowshed or stall provides. The use of covered or semi-covered yards for cattle and of open-fronted sheds for calves favours the production of healthy stock.

Ventilation of animal buildings means providing sufficient fresh air without draughts and a reasonable temperature without high humidity. Mr. King pointed out the advantages of the Belfast type of piggery, for fattening pigs, with low well-insulated sleeping quarters and yards for water and excreta which are separated from the sleeping pens by concrete baffle walls and swing doors. Such houses provide a very even temperature throughout day and night, with a maximum variation of some 12° F. With poultry kept under the intensive system, faulty ventilation is the chief error.

Mr. King concluded by advocating special attention to housing and feeding during the winter months in order to avoid the loss of condition which is so common during this period of the year.

In the discussion, Prof. J. G. Wright (University of Liverpool) mentioned the serious losses which result from cattle eating pieces of metal, such as baling wire, nails or screws. Losses from this cause are preventable. Some indication of the wide variety of such objects and the effects they produce were provided on the following day when members of the section visited the Veterinary Field Station of the University of Liverpool. E. G. WHITE

RECENT PROGRESS IN DIELECTRICS

It is something of an event for Section A (Mathematics and Physics) of the British Association to devote a session to dielectrics, as occurred on September 3 during the Liverpool meeting; but both the event and its rarity are understandable. Faraday used or knew of waxes, impregnated paper, oil, rubber, resins, silk, cotton, wood, amber, sulphur, glass, ceramics, mica and quartz. A century later vulcanized rubber (ebonite) and the phenolic and allied synthetic resins (for example, 'Bakelite') had been added; but there was little fundamental change. Engineering progress had nevertheless been remarkable, with landmarks such as the first submarine cable, insulated with gutta-percha, and Ferranti's 10-kV. cable from Deptford to London, insulated with impregnated paper, of which specimens will still support 10 kV. sixty years later.

Physics entered first in the elementary theory of the macroscopic dielectric field, leading to methods of measurement which gave some quantitative assessment of the merits of a dielectric. Unfortunately, knowledge of how to achieve merit was meagre; for example, the avoidance of electrolytes, moisture, holes, impurities and heterogeneity generally. Nevertheless, again engineering achievement, based on scanty physical principles, was impressive and made possible the great developments between the two World Wars of high-voltage plant and of telecommunications. At the end of this period the theory of the solid state began to catch up with empirical acumen, so that a directed exploration of dielectrics became practicable and, fortunately, contemporary advances in chemistry and chemical engineering made possible the economic production of new materials. The transition was gradual but the theoretical physicists, among whom Prof. H. Fröhlich, of Liverpool, must always be acknowledged, undoubtedly led the way to the general principles in what had hitherto been regarded as an experimental subject.

In the opening address of the discussion, by Dr. S. Whitehead, director of the Electrical Research Association, the following were given as the main principles so far used.

(1) Certain atoms tend to be more tightly bound in combinations and are more resistant to thermal activation, ionization and chemical attachment. In suitable groupings silicon and sulphur are preferable to carbon, the halogens to hydrogen and nitrogen to oxygen.

(2) The insulating property arises from scarcity of free electrons because there is a large energy difference between the conduction zone and the highest filled zone of electrons attached to atomic groups. The structure should therefore have as few imperfections as possible where electrons can be loosely trapped.

(3) The oscillation and rotation spectra of gases are outside the electromagnetic range, but solids and liquids have a relaxation spectrum which extends from the order of 10^{13} c./s. or above down to very low frequencies. It comprises absorption regions caused by dipoles in the molecule or in impurities (1 mobile ion in 10^{13} molecules has a noticeable effect) or by an electric moment coming from asymmetry or distortion: these regions are superposed on a comparatively weak continuous spectrum derived from a distribution of relaxation times. Dipoles in liquids can be distributed in all directions, but in solids they are usually distributed in opposite senses along a few preferred directions.

(4) Electronic instability and breakdown arises from the inability of electrons to dispose, to the solid structure, of the energy gained from the electric field. If scattering centres, such as dipoles, are present, the electric strength is higher at low temperatures because of the scattering effect; but it is less at high temperatures because the loosely trapped electrons become free. A good crystal has a fairly constant electric strength, except that of the alkali halides, which increases with temperature by reason of the unusually low Debye frequencies.

Thermal breakdown comes from failure to remove the heat generated by energy losses. If the heat has to escape through the electrodes, there is a maximum voltage which the dielectric can withstand, however thick.

With industrial insulation, discharges in holes or weak spots or over the surface often cause breakdown.

At lower voltages, breakdown frequently comes from chemical deterioration during irreversible electro-chemical actions.

(5) Long-chain molecules can provide fibrous, flexible and tough materials. Low creep and rigidity come with cross-linking—a polar crystal is a limiting case. Plastics are essentially heterogeneous; even when mainly crystalline, these regions must statistically be connected by amorphous regions.

In exemplifying these principles, reference was made to the long-chain hydrocarbons, like polythene and polystyrene, which fulfil expectations in having loss angles of merely 1–3 or 4 × 10^{-4} up to 10^{10} c./s. and can be processed. The substitution of hydrogen by fluorine yields P.T.F.E., which can be used up to 300° C., with low losses, and is much harder. By replacing a fluorine atom by chlorine, the material P.C.T.F.E. can still be used up to 200–250° C., can be transparent and flexible or translucent or more rigid, but the molecule is now asymmetrical so the loss angle is much higher. Hardening by cross-linking can be achieved with polythene by neutron bombardment in an atomic pile. Experience is scanty but this discovery is of the highest interest, because at present cross-linking is usually achieved chemically, as probably in the epoxy resins; and, although hard and adhesive materials result, they have rather high losses through asymmetry and, being built from carbon, hydrogen and oxygen, are limited in temperature. In the silicones the carbon–carbon link is replaced by the silicon–oxygen link, which fortunately seems to have so short a relaxation time that the loss angle is low except at the highest frequencies, and the advantages are gained of high-temperature operation, resistance to moisture and to discharges.

Many other examples were considered, and it was deduced that to cover all uses recourse is still necessary to the engineering methods of combining fibres such as paper, nylon, 'Terylene' and glass with impregnants such as amino-, epoxy and silicone resins on the pattern of reinforced concrete.

The miscalled ferroelectrics have many dielectric analogies with ferromagnetism, such as high and variable permeability, domains, electrostriction and a Curie point in an order–disorder transformation; but they arise from a rather accidental structure delicately poised between ionic and homopolar bonding. Furthermore, there are the anti-ferroelectrics where the low-temperature dipole moments may be oppositely oriented to cause a low polarization in this region.

The theory of electronic breakdown has had outstanding success in calculating the intrinsic electric strength from structural parameters to give agreement within experimental variation; but the range is rather restricted—from 4 to 15 MV./cm.—so that there is more practical interest in raising the working and test stresses of insulation nearer the intrinsic electric strength, whatever it may be. One of the most important developments has been in the theory of internal discharges. The accompanying practical development has lain in decreasing the number and size of voids and by increasing their electric strength by fluid pressure. In good capacitors and, more notably, in the thick insulation of the high-voltage pressure-type cable, transient stresses have been withstood approaching one-half the intrinsic electric strength. Since the discharges are repeated every cycle, the development of cables and other gear which work at quite high radio-frequency electric stresses is extremely creditable.

Practical success in a very thin dielectric, which would have essentially a high electric strength, has been elusive; but an oxide film shown at the meeting gives some hope.

Low-voltage apparatus fails most often by electrochemical deterioration, and great ingenuity has been shown in the chemical–physical field in solving this problem. An example was given of a nascent-hydrogen acceptor which prolongs the life of certain insulation five- to thirty-fold.

During the meeting, Dr. B. Szigeti, of the University of Liverpool, indicated that although Fröhlich's theories gave the conditions for breakdown and very often permitted the successful calculation of the electronic electric strength, there is a great deal more to examine in the detailed mechanism. The theoretical physicists would secure great help from accurate information of time-lags in breakdown and the growth of pre-breakdown currents. The experimentalists, however, find extreme difficulty both in the measurements and in defining what they are measuring. Dr. Whitehead had already mentioned that, in certain connexions, whether Fröhlich's 'amorphous' or 'crystalline' theory applies is determined by the presence or absence of dipoles rather than the degree of crystallinity.

Dr. Whitehead defended the protracted consideration which engineers often have to give to projects strongly favoured by scientific argument, owing to the many associated problems which have to be solved and the grave consequences of error. Prof. A. M. Tyndall wound up the meeting in expressing his satisfaction that studies in theoretical physics (begun in his department at Bristol) had contributed so fruitfully to engineering practice and progress.

FERTILIZER RESPONSES IN EAST AFRICA

By Dr. D. W. DUTHIE

East African Agriculture and Forestry Research Organization,
Kikuyu, Kenya

PRIOR to 1939, field-trials had proved the value of phosphates on wheat in the Kenya Highlands, but there appeared to be little prospect of chemical fertilizers finding a place in African farming. After the War, however, it became clear that food production in East Africa could not keep pace with the rapidly increasing population, and funds were provided, from local sources as well as from the Colonial Development and Welfare Scheme, to extend the field and laboratory studies of fertilizer response on African as well as European farms. Existing knowledge and experience were collected at a conference in 1949[1] at which preliminary results of the new experiment schemes were reported. In February 1953 a second conference was held at the headquarters of the East African Agriculture and Forestry Research Organization, Muguga, Kenya, to discuss the work of the previous three years and to review the present position. This meeting was under the chairmanship of Sir Bernard Keen, director of the Organization, and included members of the research staff of his Organization as well as specialist officers from the Departments of Agriculture of Kenya, Tanganyika, Uganda and Zanzibar, and from the Empire Cotton Growing Corporation, the Overseas Food Corporation, the Tea Research Institute of East Africa, and African Explosives and Chemical Industries, Ltd. Dr. E. M. Crowther, deputy director of Rothamsted Experimental Station, and Prof. M. Stelly, of the Agricultural College, University of Georgia, United States, attended the meeting by invitation.

A great deal of attention was focused on the effects of phosphatic fertilizers on food crops, since the exploitation of a deposit of primary phosphate (francolite) at Tororo in Uganda is now being carried out on a commercial scale. It is clear that the raw Uganda rock phosphate is not suitable for application as a fertilizer if immediate responses are required; but it shows residual effects which may be of importance in indirect manuring of crops by fertilizing grass leys in the rotation. During the War a modification of the Rhenania process was developed in which the rock phosphate was calcined with crude sodium carbonate from Lake Magadi in Kenya; the resulting product—usually called sodaphosphate—contains a high proportion of citric-soluble phosphate averaging 18 per cent out of a total phosphate content of about 21 per cent. In pot culture experiments the phosphate in sodaphosphate was almost as effective as the superphosphates, but in field-experiments considerable variation was obtained in comparative responses. One group of field-trials showed sodaphosphate to be about 5 per cent less effective than superphosphate, while in another group it was little more than half as effective, both comparisons being made on equivalent dressings of citric-soluble phosphate. Improved methods of manufacture, possibly with concentration of the raw material before processing, may increase the effectiveness of sodaphosphate and reduce the size of dressing required.

It appears that the more acid, leached, highly coloured soils give responses to phosphate, whereas the pallid soils do not normally react so well. This generalization is by no means straightforward, since other factors, as yet unexplained, may affect the response. For example, at least one area was noticed in Kenya in which something prevented the higher yield which was indicated by observation of the crop in its earlier stages, and it has been suggested that deficiency of zinc or copper may possibly be a factor in phosphate responses in some parts of East Africa.

Of the crops studied, wheat seems to give the most clear-cut responses to phosphate, 500 lb. sodaphosphate or 160 lb. double superphosphate per acre being the recommended dressings where phosphate is required. Among other food crops, sorghum responds better than maize, and maize better than finger millet; sweet potatoes have given very little response. In Zanzibar, applications of phosphate to pine-apples did not give positive responses, and even tended to decrease yield, but on one soil type (*changa*) as much as 100 per cent increase in the yield of maize, and nearly 300 per cent increase in sunflower yield, were obtained from 2 cwt. single superphosphate per acre, while 3 cwt. caused a 200 per cent increase with rice. In field trials carried out by the Overseas Food Corporation, groundnuts responded to phosphate in all areas, the average increase in yield being about 100 lb. kernels per acre with a dressing of 0·5 cwt. phosphate; some evidence was obtained that half this dressing would be nearly as effective. In sisal trials, phosphate has not so far caused increases in yield of fibre, but experiments have recently been planted on exhausted land, and the results of these may reopen the question. There is some evidence that phosphate reduces chlorotic mottling, and on certain soil types it is useful in establishing young sisal. With pyrethrum, 300 lb. per acre double superphosphate, placed at the base of the ridge before planting, gave striking responses in the Southern Highlands of Tanganyika; but in Kenya the effect of phosphate applied in the planting holes was to cause a short-lived increase in flower production during the first season only. Coffee did not respond to added phosphate by giving increased yields, although evidence was obtained that the plants had taken up additional phosphate.

The method of application of phosphate is particularly important in East Africa, and with grain crops it seems to be essential to place phosphate below the seed or to drill it in with the seed; when it is broadcast or applied between the rows it stimulates the growth of weeds, which may smother the crop plants before their roots can reach the fertilizer.

At Muguga, laboratory work on the chemical aspects of phosphate manuring has shown that, although fractionation of the soil phosphate into 'acid-soluble' and 'adsorbed', by the method of Bray and Kurtz, provided some relationship with field response to phosphate, the percentage saturation of the base exchange capacity of a soil could give a better forecast of its reaction to applications of phosphatic fertilizers. Recently, a relationship has been found between the citric-soluble silica in the soil and the effect of added phosphate; but the meaning of this is not yet clear.

Physiological studies at Muguga of the mineral nutrition of maize and sorghum demonstrated a marked interaction between nitrogen and phosphorus. A state of balance between nitrogen and phosphorus can be established at many different levels of supply, but of course the highest suitable level produces the largest plant. Field experiments by the Overseas Food Corporation confirmed these laboratory results, since with both maize and groundnuts nitrogen and phosphate together gave much better responses than either alone. Fertilizer trials carried out by the East African Agriculture and Forestry Research Organization in African areas showed that, with maize, sorghum and millet, the effect of added nitrogen was greater on pallid soils, on which phosphate gave little response, as compared with highly coloured soils which responded definitely to phosphate.

In field-trials in the European Highlands of Kenya, laid down jointly by the Department of Agriculture and African Explosives and Chemical Industries, it was found that the application of nitrogen to maize at tasseling had a consistently beneficial effect, and it is suggested that ½–1 cwt. sulphate of ammonia both at planting and at tasseling would be an economical dressing on many soils. The Uganda Department of Agriculture reports striking responses by maize to sulphate of ammonia, one field-trial giving 66 per cent increase with 2 cwt. per acre, while 4 cwt. gave 97 per cent increase; in another experiment where the control yield of maize was 3,400 lb. per acre, a 50 per cent increase was caused by 2 cwt. sulphate of ammonia. In Zanzibar most soils respond to nitrogen, increases in maize yield as high as 80 per cent being given by 1 cwt. sulphate of ammonia per acre. Sorghum has also given marked responses in Zanzibar, a 50 per cent increase with 1 cwt. and 200 per cent increase with 3 cwt. sulphate of ammonia being on record; rice has given even greater responses, one experiment on Pemba Island giving a five-fold increase due to sulphate of ammonia.

In the Kenya Highlands, wheat did not give worthwhile increases in yield with sulphate of ammonia, but it seems possible that some other factor is limiting growth and yield, and this requires further investigation. Pine-apples in Zanzibar gave good responses to nitrogen, both the number and the size of fruit being increased during the first two seasons. In Uganda cotton benefited from the application of 2 cwt. sulphate of ammonia at flowering, but the increase in yield was not economic. In that area the action of nitrogenous fertilizers is obscured by a build-up of soil nitrate during fallow or resting periods, and investigations are now being carried out on the nitrogen cycle in the soil. In the Lake Province of Tanganyika, where cotton is rotated with bulrush millet, a top dressing of nitrogen following organic manuring raised the yield in the year of application only, but an increase of this kind would not attract African peasant farmers, since the risk of crop failure through drought and other causes would make them hesitate to put actual cash into the crop.

In both Kenya and Tanganyika, pyrethrum gave uneconomic responses to nitrogen, and in several trials it delayed flowering or decreased the final yield significantly. With sisal, too, economic increases in the yield of fibre have not resulted from applications of nitrogen, although growth records have indicated that nitrogen hastens the growth of the plant. Experiments by the pasture research section of the Kenya Department of Agriculture have shown that sulphate of ammonia increases the yield and the feeding value of both grass leys and established pastures, but in these trials a surprisingly rapid and definite increase in soil acidity was found when the heavier dressings of sulphate of ammonia were applied. Methods of extending the growing season, and of preserving grass and other bulk feeds, are being tested, since increases in grass production only during the normal season would accentuate the lack of feed during the rest of the year.

In most parts of East Africa no significant responses to potash were obtained with maize, sorghum and millet; but on the coastal belt of Tanganyika there were important potash effects on maize and sorghum in the second and third seasons. On one of the Zanzibar soil types (*kinongo*) potash has occasionally given excellent responses with maize and sorghum, and there is strong evidence that potash assists cereals to grow away from borer attack. Significant responses to potash on wheat are recorded from the Southern Highlands of Tanganyika, and potash combined with phosphate gave marked increases in yield, but the cost of treatment is high (£5–8 per acre) owing to the long road haul from the nearest railhead, and the expenditure may not be worth while in view of the risks of crop failure. In Kenya, small significant increases in yield of wheat were caused by potash in one year, but in the two following years the response was negligible, and it is possible that this transitory effect was due to the particular seasonal conditions in the first year. Even when no yield increases were obtained, the grain from the potash plots was noticeably plumper than that from other treatments.

Both in Kenya and Tanganyika, potash had no definite effects on the yield of pyrethrum flowers; it was thought at one time that lack of potash might be connected with the incidence of Ramularia bud disease, but no conclusions on this point can yet be drawn. Tobacco experiments in the Southern Highlands of Tanganyika showed increases in yield which were directly dependent on the amount of potash applied, and the highest yields were given by a balanced NPK mixture which produced more than 78 per cent of high-grade leaf. Coffee gives no response to potash in East Africa, and on the whole most tea soils are well supplied with potash, but the tea crop drains the potash reserves, since the K_2O content of the tea 'flush' may be as high as 2·5 per cent.

Healthy sisal in Tanganyika does not seem to respond to potash, and it has been noticed that excess potash results in acute chlorotic mottling even if lime and phosphate are adequate. This is curious in view of the fact that banding disease, which is prevalent in parts of Tanganyika, is primarily due to potash deficiency, and several estates are now applying potash as a routine. It has been suggested that the soil K/N ratio is important in controlling the uptake of potassium by plants, and that a K/N ratio of 0·05 is critical.

Applications of lime have given increases in yield in a few field trials, but on the whole liming has not given responses in East Africa with wheat, maize, sorghum, groundnuts, pyrethrum or coffee. There is some evidence that Kenya soils are not likely to react to lime when they are less acid than *p*H 5·2, but above this acidity there is no certainty that liming will be beneficial. Sisal is a gross calcium feeder, and continuous sisal growing on red earths leads to progressive acidification of the soil. Chlorotic mottling of sisal is reduced by applications of limestone, and it seems possible that this disease is related to excessive uptake of minor elements; excessive cobalt has been reported in leaves showing chlorotic mottling. It is sometimes stated that sisal plants grown on soil which is low in calcium tend to be more susceptible to bole rot; but a definite association between the two has not yet been confirmed.

With organic manures, the most striking results were obtained on hill sands in the Lake Province of Tanganyika, where the residual effects of cattle manure at 3 or 7 tons per acre have persisted for eight years on cotton rotated with bulrush millet. Equivalent amounts of nitrogen and phosphate gave results similar to, or greater than, these organic dressings, but only in the year of application. Cattle manure is particularly effective on the highly leached soils of the thinly populated upper Kikuyu bracken lands in Kenya, where applications of the major fertilizers are not very effective. In addition to these striking and as yet unexplained effects of organic manures, there appears to be an overall response to cattle manure and compost on most food crops in most areas of East Africa. The fact that cattle manure is not widely used by African farmers is probably explained by the labour involved in transport and application, and it may be the comparative lack of wheeled transport that is the underlying cause of this reluctance to return plant and animal residues to the soil.

With coffee, mulching has proved to be much more effective than compost or cattle manure, both in Kenya and in Tanganyika. From studies of the soil moisture relationships it has been shown that the effect of mulching is far greater in assisting the penetration of rain than in impeding evaporation during the dry season. Thus coffee planters are advised to apply mulch at the onset of the rainy season, field trials having shown that the yield in a dry year could be increased by 100 per cent, while a 75 per cent increase may be obtained in a year of normal rainfall.

The microbiological aspects of the nitrogen cycle in soil are being studied at Muguga, since it has been recorded by the Uganda Department of Agriculture that large amounts of nitrate (up to 300 p.p.m.) can accumulate in the top inch of bare fallow soil, with a sharp drop to 50 p.p.m. in the second inch and a rise to 300 p.p.m. at a depth of about 3 feet. In shaded or mulched soil only very small amounts of nitrate are found (less than 10 p.p.m. in the top six inches), while cropped soils show varying amounts, less than bare fallow but more than shaded soils. The basic explanation of these field-results is not yet complete, since they do not fit into the usual pattern of microbiological action, and further work, in both field and laboratory, is being carried out.

For some years deficiencies and excesses of minor elements, in both crops and stock, have been suspected in East Africa, but it is only recently that facilities for spectrographic estimation of these has been made available. Zinc deficiency may be involved in phosphate response, copper deficiency in coffee has been indicated by growth responses to fungicidal sprays containing copper, excess cobalt has been reported in sisal leaves showing chlorotic mottling, and some evidence of calcium deficiency caused by excessive uptake of manganese has been found in coffee in Tanganyika. A recent observation by the Fisheries Research Organization that the waters of Lake Victoria are abnormally low in sulphur points to the need for study of this element in the crops and soils of the vast drainage basin of that lake.

TENTH INTERNATIONAL PHYTOGEOGRAPHICAL EXCURSION

THE International Phytogeographical Excursion held in Spain this year was the tenth of the series which began in the British Isles in 1911; it consisted of two parts, the first starting from Barcelona on June 25 and ending at Madrid on July 15, and the second beginning at Madrid on July 16 and returning there on July 22. Twenty-six visiting botanists of twelve different nationalities took part, some for both parts of the excursion, some for only one, in addition to Profs. Don Salvador Rivas-Goday and Don Fernández-Galiano, who led the party, and other Spanish botanists who accompanied it for varying periods in the districts of which they had special knowledge. Dr. Werner Lüdi, the well-known Swiss phytogeographer and chairman of the international committee responsible for organizing the excursions, was the director on this occasion. Like its predecessors, the excursion in Spain was both scientifically profitable and enjoyable. Much ground was covered, as the route extended from Barcelona in the north-east to Lugo in the north-west and the Sierra Nevada in the south, so inevitably there was little time for intensive study of any one locality or of the numerous and fascinating ecological and phytogeographical problems which arose at every step. Nevertheless, all who took part in the excursion felt that they had enjoyed an incomparable opportunity of seeing a number of representative and very diverse regions of a country which has perhaps no equal in Europe as a field for ecological study.

The party travelled in a diesel motor-coach, large enough to accommodate them all, together with a technical assistant and the baggage, and the skill with which the drivers of this somewhat cumbrous vehicle negotiated narrow and difficult mountain roads was quite remarkable. This method of travel not only allowed the maximum freedom in the choice of route but also allowed stops to be made for photography or note-taking wherever the vegetation seemed particularly interesting.

The first area studied was the curious rocky ridge of Montserrat, which made an excellent introduction to the rich flora of the coastal region of Catalonia with relatively luxuriant maquis vegetation depending on mild winters and not excessively dry summers. From there, travelling via Lérida to Saragossa, the party crossed the arid region of los Monegros in Aragon, where a rainfall of less than 300 mm., combined with cold winters, very hot summers and a porous gravelly soil (derived from alluvial beds of Oligocene age), gives rise to a very scanty covering of vegetation. Xerophytes such as *Capparis spinosa*, *Peganum harmala* and *Lygeum spartum* are common; but though the vegetation has the appearance of a very dry steppe, almost of a semi-desert, occasional relics of *Quercus ilex*, *Pinus halepensis* and *Juniperus thurifera* show that the climax is woodland and that the Spanish botanists are right in terming it a 'pseudo-steppe'. The potentially most fertile land in this dry region lies, of course, in the moister hollows and river valleys, but cultivation is often prevented or impeded by high concentrations of gypsum and other salts. Many of the damp hollows are still occupied by a natural vegetation of halophytes such as *Salicornia* sp., *Suaeda fruticosa* var. *brevifolia*, etc., but where irrigation water is available rice is successfully cultivated.

After a brief visit to the central Pyrenees, including the impressive National Park of Ordesa, the excursion continued north-westwards to Pamplona and then via Logroño and Soria to Burgos. The journey along the southern foothills of the Pyrenees was an interesting demonstration of the gradual change in the vegetation from the dry continental conditions of Aragon to the moister and more Atlantic conditions of Navarre. Atlantic plants such as *Erica vagans* and many of the common British wayside species gradually increased in abundance, and near Pamplona meadows of true sward-forming grasses at low altitudes were seen for the first time. Evidence of a still more markedly Atlantic climate was seen in the highlands of the Macizo Ibérica between Logroño and Soria, where at altitudes above 1,000 m. there are extensive heaths of *Calluna*, *Erica aragonensis*, etc., reminiscent of the moorlands of Ireland and Scotland. Some characteristically 'British' plant communities, such as a 'wet heath' with *Nardus*, *Juncus squarrosus*, *Sphagnum* spp., etc., were met with here.

After Burgos the route, before turning south-east towards León and Castile, passed through the Cantabrian mountains to the Asturias and Galicia, the region of Spain with the most strongly developed oceanic climate and vegetation. The luxuriant roadside vegetation of the Asturias with its abundance of *Daboecia*, species of *Erica* and, in places, of *Osmunda*, recalled Cornwall and south-west Ireland, though the fields of maize and the vines around the houses testified to higher summer temperatures. It was interesting to see, in the Asturias, enclosed fields and hedgerows similar to those of England, as well as a *Quercus petraea* woodland association floristically very similar to that in Great Britain. The change from the Atlantic conditions of Galicia to the relatively dry and continental climate of León and the still drier climate of north-western Castile was sudden and very striking, though it was interesting to note that familiar British plants such as *Juncus* spp. persisted in edaphically moist habitats.

From Madrid the Sierra de Guadarrama, with its interesting endemic montane flora, was visited, and then in the second part of the excursion the route turned south across the monotonous and intensively cultivated plains of La Mancha towards Andalusia. The gorge of Despeñaperros in the Sierra Morena which forms the frontier between Castile and Andalusia showed a striking change in the flora, and various southern species were seen for the first time. In the Guadalquivir valley near Córdoba the extensive fields of cotton were a remarkable sight for northern European botanists. The most memorable day on the second part of the excursion was the visit to the Sierra Nevada and the ascent of the Picacho de Veleta (3,470 m.), which is readily accessible by a road almost reaching the summit. The beautiful and varied alpine flora at altitudes above 2,500 m., with its abundance of rosette plants and small spiny shrubs, seemed very strange to most members of the party, and very few of the species were familiar to those who had not visited the area before; one member of the party said that botanizing here was like "botanizing on the moon".

To an English botanist the foremost impression of this rapid survey of the flora and vegetation of Spain was of the immense wealth of species and the high degree of endemism. Travelling as we did, rapidly from place to place, the flora seemed to be inexhaustible and changed every day, even when the climatic and other conditions seemed to be similar. Everywhere endemic species, restricted to the Iberian Peninsula, or to some part of it, appeared to play a prominent part in nearly all the plant communities.

Another vivid impression was of the universal ecological importance of soil conditions. In all climatic regions of Spain, both dry and wet, and at all altitudes, there was a marked contrast between the flora of calcareous and non-calcareous soils, and no evidence was seen supporting the view that edaphic factors are less important in Continental countries than they are in the British Isles. Though the distinction of the calcicole and calcifuge floras was always apparent, the soil preferences of individual species were not always the same as in Britain. Thus

Rhamnus catharticus, regarded in Britain as a typical calcicole, grows in the Sierra de Guadarrama on poor acid soils, and what a British botanist would regard as strange mixtures of calcifuge and calcicole species were sometimes encountered.

It was of great interest to see the ecological range of some of our British plants in climates very different from our own. Some British species appeared to be extremely versatile, and one gained a new respect for the capabilities of such plants as *Jasione montana* when seeing them growing with Mediterranean xerophytes such as *Dorycnium suffruticosum* and *Halimium umbellatum*. In Soria province it was odd to see *Arctostaphylos uva-ursi*, regarded by British botanists as a typically northern plant, growing in pinewoods at no great altitude in company with typically Mediterranean shrubs such as *Erica arborea* and *Lavandula stoechas*.

It was not surprising to find that in the arid regions of Spain some plants which in Britain are confined to dry habitats require moist soil conditions; thus *Blackstonia perfoliata*, which in Britain grows in relatively dry habitats, in the arid climate of los Monegros is restricted to damp places.

The excursion gave its members not only a unique opportunity of studying the natural and semi-natural plant communities of Spain, but also many fascinating glimpses of agricultural practices and the way in which these varied in the different regions. Many members were particularly interested in the peculiar system of shifting cultivation on the poor hill soils in Galicia where a long fallow stage of the tall leguminous shrub *Sarothamnus welwitschii* often intervenes between periods of cultivation of cereals and other crops. The *Sarothamnus* is cut for litter, and its seeds are sown with those of the cereal crop.

It is a pleasure to mention the generous hospitality which the members of the excursion everywhere received. Not only were the two leaders of the party, Profs. Rivas-Goday and Galiano, of the Faculty of Pharmacy, University of Madrid, unsparing in their efforts to help their foreign guests and answer their many questions, but also, in all the larger towns visited, hospitality was offered on a most generous scale. Since in Spain botany is generally linked with pharmacy, it was usually the local associations of pharmacists (Colegios de Farmacéuticos) to which the excursion was indebted for this hospitality, which not only included splendid banquets and official visits to places of scientific or artistic interest, but also such delightful features as displays of traditional dancing in Córdoba, Oviedo and Saragossa. The warmth of this welcome as well as the beauty and interest of the landscapes and the plants will make the Tenth International Phytogeographical Excursion live long in the memories of those who took part in it.

P. W. Richards

NEWS and VIEWS

Architectural Science at Sydney: Dr. H. J. Cowan

Dr. H. J. Cowan, lecturer in civil engineering in the University of Sheffield, is shortly to take up his appointment to the newly created chair of architectural science in the University of Sydney. Born in 1919, he graduated with first-class honours in the University of Manchester in 1939, obtaining his master's degree a year later. From 1940 Dr. Cowan served in the Royal Engineers until he was wounded in Holland in 1945. After gaining experience with firms of civil engineering contractors and structural designers, he joined the teaching staff of University College, Cardiff, where he remained until he went to his present post in 1948. Since going to Sheffield, Dr. Cowan has carried out researches in reinforced and prestressed concrete and has published a number of papers and articles on these subjects in Britain and in the United States. His work on reinforced and prestressed concrete in combined bending and torsion is a noteworthy contribution in a new field of investigation, and for a thesis embodying some of this work he was awarded the Ph.D. degree. Dr. Cowan has taught structural engineering to students of architecture for the past five years, and he has delivered courses of public lectures on the theory of prestressed concrete design and on the design of concrete for ultimate strength.

British Occupational Hygiene Society

The British Occupational Hygiene Society has recently been formed and will hold its first conference at the London School of Hygiene and Tropical Medicine on November 2. Proceedings will be opened by the Minister of Labour, Sir Walter Monckton, at 11 a.m.; Dr. T. Bedford will then deliver his presidential address. During the afternoon the following papers will be read and discussed: "Measuring the Worker's Environment", by S. A. Roach, "The Problems of Chemical Toxicity", by D. G. Harvey, and "Occupational Hygiene and the Industrial Designer", by J. E. Braham. The Society hopes to promote knowledge of all matters which have a bearing on the health of men and women at their daily work. Regular conferences will be held at which both general problems and special technical aspects of occupational hygiene will be discussed. Particulars are available from the honorary secretary, Mr. P. C. G. Isaac, Public Health Engineering Laboratory, King's College, Newcastle upon Tyne, 1.

National Smoke Abatement Society: Annual Conference in Glasgow

The twentieth annual conference of the National Smoke Abatement Society will be held in the Banqueting Hall, City Chambers, Glasgow, during September 30–October 3, and will be attended by some four hundred and fifty members and delegates, drawn mainly from local authorities, government departments and the fuel and power industries. On the first day the president of the conference, Prof. F. E. Tylecote, emeritus professor of medicine in the University of Manchester, will give his address, which will be on smoke and the local authority. This will be followed in the afternoon by the Des Voeux Memorial Lecture, which will be given by Sir John Charles, chief medical officer, Ministry of Health, who will speak on air pollution in relation to preventive medicine. The sessions for the remaining two days will deal with the following subjects (with the speakers shown in brackets): the London fog disaster of December 1952 (Dr. J. A. Scott, Dr. A. Parker and Arnold Marsh); report on smokeless zones (Dr. T. M. Clayton); production and use of solid smokeless fuels (Dr. F. J. Eaton, G. E. Hall and Islwyn Jacob); availability of solid smokeless fuels (J. O. Cooke, H. H. Prosser, Eric J. David and Commander C. Buist); and the efficient and smokeless combustion of fuel oils (K. H. Sambrook). The formal sessions of the conference will end with the annual general meeting of the Society, after which there will be an afternoon tour of the Loch Sloy power station and dams. Further information can be obtained from the Society at Chandos House, Buckingham Gate, Westminster, London, S.W.1.

Colonial Development Corporation: Statement of Accounts for 1952

The annual report of the Colonial Development Corporation and statement of accounts for the year ended December 31, 1952 (No. 158; pp. 62; London: H.M.S.O., 1953; 3s. 6d. net), records that the expectation that 1951 would constitute the peak of loss has not proved correct: in spite of Lord Reith's drastic pruning, £638,747 was lost in trading compared with £643,404 the previous year, the consolidated operating loss being £1,097,091 as against £1,070,043. With losses on realization of assets of abandoned projects, the total Corporation deficiency of £3,805,208 (compared with £2,905,290 in 1951) brings the cumulative deficiency to £8,399,807. It is now emphasized that, in long-term development, while failures must be expected to show up first, successes often mature slowly and ten to fifteen years may be required before preliminary troubles are overcome, full production reached and a profit shown. Some projects are treated as passing from the development stage to the trading stage at a point when initial trading losses must be expected. Another eight projects were abandoned during the year, the largest being the Gambia Rice Farm; and, of nine new projects, five are merely investigations and the others are loans involving no field-work by the Corporation. The Corporation has no accumulated fund to absorb trading losses, and it is proposed that in future new projects will only be taken up on a strictly commercial basis. This is likely to exclude some types of desirable development such as agricultural settlement schemes; but, while it is recognized that application of a commercial criterion to the Corporation's general funds is salutary, the suggestion is made that the Corporation should be allowed to finance some projects which are socially valuable but are unlikely to be profitable, and that these investments should be recorded separately in its accounts and their results judged on other than a profit basis. Between December 31, 1951, and March 1, 1953, senior staff in the United Kingdom was reduced by 33 per cent and junior staff by 19 per cent. Of the United Kingdom staff of 248 on December 31, 1952, 80 were executive. Of the overseas staff of 19,000, 3,900 were executive: agricultural projects claimed 8,450; animal products, 1,000; factories, 1,100; fisheries, 150; forestry, 4,200; minerals, 2,000; and construction, 1,600.

Aeronautical Research in Academic Institutions

The February issue of the *Aeronautical Quarterly* (4, Part 2; 1953) is an unusual number in that all but one of the contributions are from colleges or universities, and it is therefore interesting to gain from the contents an indication of the nature of the aeronautical research which is pursued in academic circles. The paper by A. Powell on the noise emanating from a two-dimensional jet above the critical pressure is a report on one part of the fundamental research being conducted at the University of Southampton into the nature—and amelioration—of jet noise; the physics of some oscillatory phenomena is being carefully investigated. Some of G. E. Gadd's work as Beit Scientific Research Fellow at the Imperial College of Science and Technology, London, is described under the heading of some aspects of laminar boundary-layer separation in compressible flow with no heat transfer to the wall; an analysis has been made which suggests that, with the types of pressure distribution most usual in practice and free stream Mach numbers up to 10, no serious errors would be introduced into the calculation of the separation-point of a laminar boundary layer by the assumption of the value unity for the Prandtl number and also for the index of the variation of viscosity with absolute temperature. The Department of Aeronautical Engineering in the University of Sydney is represented by a paper from Dr. W. H. Wittrick on the buckling of oblique plates with clamped edges under uniform compression; this is a piece of theoretical work, the need for which has come about with the introduction of swept-back wings. F. G. Irving's paper on the theory of the constant-area mixing of compressible flows as applied to high-speed wind-tunnel design contains a theory which was derived during the design by the author of the supersonic wind tunnel at the Imperial College, London, and the theory checks well with experiment in this tunnel and in one of the tunnels at the National Physical Laboratory, Teddington. Dr. Bryan Thwaites, of Winchester College, who earlier had contributed a rapid method of designing a ducted fan for a given performance, has a note on the performance of ducted fans in which is given the extension to the inverse problem of determining the flow past a given fan in conditions other than those of the design; the method is again rapid. K. E. G. Wieghardt, formerly of the Admiralty Research Laboratory and now of the University of Hamburg, suggests a useful parameter in the presentation of the many experimental results of the resistance of screens in a paper of that title. The *Aeronautical Quarterly* will now appear at six-monthly intervals. This may well be a sign of the times, since much of the expanding volume of aeronautical research is of a confidential nature.

Research Fellowships in the United States for Young European Scientific Workers

In response to a request from the Organization for European Economic Co-operation, the United States Government, through its Foreign Operations Administration, has provided funds of more than a million dollars to enable a hundred and fifty outstanding young scientific workers from Europe to travel to and live in the United States for up to two years in order to study and gain experience in American research institutions. By this means it is hoped to advance scientific research and to facilitate the adoption of the results of scientific research in production techniques. The funds are available in the first instance until the end of 1955, and the scheme is being administered by the National Academy of Sciences, Washington, D.C. Successful candidates, who will be required to undertake to return to their own countries and resume their scientific work there on completion of tenure of fellowships, will, for the most part, participate with their American colleagues in the current fundamental scientific research programme at the particular institution; but opportunities may also be provided towards the end of the tenure of the fellowship for work on problems in industrial or other laboratories in applied research related to the fundamental research they have previously carried out. For the United Kingdom about twenty-five fellowships will be available, and the selection will be made by the Royal Society. No age-limits are specified, but it is expected that most of the fellowships will be awarded to persons about 26–32 years of age. Candidates who propose to do research in the natural sciences and in the engineering, agricultural and medical sciences, but excluding clinical medicine, will be considered; they must have a doctorate in science or the equivalent experience. Applications, which may be made at any time, will be considered at regular intervals; for the first two sets of applications the closing dates are, respectively, October 1 and November 30. Application forms and further information can be obtained from the Assistant Secretary, Royal Society, Burlington House, London, W.1.

In recognition of the contribution to Anglo-American understanding made by King George VI, the English-Speaking Union of the United States has established memorial fellowships to enable British men and women (aged 17–29 years) to continue their scientific and technical education in the United States. Twenty-five fellowships have been established for the academic year 1954–55, and each is valued at 2,500 dollars. Further information can be obtained from Mrs. D. R. Dalton, King George VI Memorial Fellowships Committee, English-Speaking Union, 37, Charles Street, London, W.1.

Mammoth Hunters in Austria

The sixth volume of the ***Mitteilungen der Prähistorischen Kommission der Österreichischen Akademie der Wissenschaften***, published in Vienna, 1952–1953, includes a long article on a group of prehistoric home sites containing a quantity of mammoth bones and stone implements which were investigated some little while ago by the late Drs. J. Bayer and H. Obermaier. The sites are near Langmannersdorf on the Perschling in the region of St. Polten. The implements recall those found at a somewhat similar mammoth-hunter site at Unter Wisternitz in Moravia, some miles from Brno. The fauna comprises bones of wolf, fox, mammoth and some small rodents, as well as those of hare and rhinoceros. The stone industries are of the late Aurignacian (late Gravettian) type normal for the region. They are well illustrated in fifteen full-page drawings. There are also some half-tone illustrations of the sections cut and some of the finds of bones. A detailed inventory of the objects unearthed concludes the paper.

Mutual Inhibitory Effects in Nodule Formation

P. S. Nutman has shown that the number of root nodules formed on clover, in test-tube culture on agar, depends directly upon the volume of the medium and inversely upon the number of seedlings present per unit volume of medium (*Ann. Bot.*, N.S., 17, 65, 95; 1953). Plants which form nodules early in seedling development inhibit nodule formation on an associated plant more strongly than plants which normally form nodules later. Among all the types of plants examined, for example sparsely or abundantly nodulating plants, the mutual inhibiting effects when grown in pairs were found to be the same, notwithstanding large differences in plant size. Similar inhibitory effects were observed in the presence of non-leguminous plants; for example, lettuce and flax reduced nodulation on clover plants but to a lesser extent than companion clover plants. Comparable results were obtained in experiments with lucerne and vetch. These and other interesting observations are fully described and discussed. The hypothesis is advanced that bacterial infection and nodule formation may be inhibited by specific root secretions.

National Institute of Agricultural Botany, Cambridge

Vol. 6 of the *Journal of the National Institute of Agricultural Botany* contains, besides various technical papers and results of its cereal and brussels sprouts trials, a full report of the Institute's first crop conference held last December. On this occasion the suitability of different varieties of wheat, fodder-beet and potatoes for growing in Great Britain was discussed, and much information that had been accumulated over a long period of years was brought together for the first time. The subject in each case was considered from a number of aspects, so that the farmer may judge for himself what type of crop may best suit his own set of conditions. The volume also includes the 1950–51 report of the Seed Production Committee and that of the 1952 Conference of Seed Analysts. In an appendix to the latter, a suggestion is made that expression of weed seed impurities by number per ounce rather than percentage by weight, as at present, would give a better indication of the value of a seed sample. Weed seed content also forms the subject of a detailed survey made by the Official Seed Testing Station of the samples submitted to it over a long term of years. The results show that, since 1923, definite changes in the impurities recorded have occurred. These seem to be largely associated with changes in the sources of supply of the crop seed and particularly with the greatly increased home production of grass and clover seed.

Spectrographic Study of the Double-lined Binary System H.D. 27483

A spectrographic study of the double-lined binary system *H.D.* 27483 has been made at the Dominion Astrophysical Observatory, Victoria, B.C., and Ruth J. Northcott and K. O. Wright have published the final results from plates taken at the Dominion Astrophysical Observatory, the David Dunlap Observatory and the Mount Wilson Observatory—a total of eighty-eight plates in all—for this system (*Contrib. Dom. Astrophys. Obs.*, Victoria, B.C., No. 25; 1952). The orbital elements have been determined, the final period being 3·05911 days and the eccentricity 0·017 ± 0·006 (incidentally, it is worth noticing that this is close to the eccentricity of the earth's orbit). The physical characteristics of the system show that the mass of the system is 0·97 that of the sun, the radius *a* of the orbit $3·95 \times 10^6$ km., the inclination of the orbit 51°, the magnitude 6·86 and the absolute magnitude 4·0, the effective temperature 6,570° K. and the spectrum *F5*. These figures refer to the primary component and are nearly the same for the secondary component, the mass of which is 0·959 that of the primary and its absolute magnitude 4·1. While the data indicate that the system is quite normal, the luminosities, according to the Russell diagram, are lower than the average for the spectral type.

Colonial Service: Recent Appointments

THE following appointments have recently been made in the Colonial Service: W. J. Blackie (deputy director of agriculture, Fiji), director of agriculture, fisheries and forestry, Hong Kong; E. S. Capstick (senior agricultural officer, Trinidad), deputy director of agriculture (crop husbandry), Trinidad; R. C. Michaelides (agricultural superintendent, class *F*, Cyprus), agricultural officer, class II, Cyprus; B. G. Montserin (chief scientific officer, Trinidad), deputy director of agriculture (research), Trinidad; I. C. Papadopoulas (temporary agricultural superintendent, class I, Cyprus), agricultural officer, class II, Cyprus; E. J. Shrubshall (deputy director of forests, Federation of Malaya), director of forests, Federation of Malaya; W. K. M. Mitchell (agricultural officer, Jamaica), senior agricultural officer, Jamaica; D. R. Wilson (statistician, East African Statistical Department, East African High Commission), deputy government statistician, Nigeria; B. O. L. Duke, medical research officer, Grade III, Nigeria; G. W. Ivens, senior scientific officer (botanist), Colonial Insecticide Research Unit, Tanganyika; W. Wilkinson and R. M. C. Williams, scientific officers (entomologists), East African High Commission; A. W. Anderson, veterinary officer, Gambia; A. G. Warren, veterinary research officer, Nyasaland; G. Usher, plant pathologist, Gold Coast.

The Night Sky in October

NEW moon occurs on Oct. 8d. 00h. 40m., U.T., and full moon on Oct. 22d. 12h. 56m. The following conjunctions with the moon take place: Oct. 5d. 13h., Mars 5° N.; Oct. 5d. 15h., Venus 5° N.; Oct. 9d. 10h., Saturn 8° N.; Oct. 10d. 01h., Mercury 3° N.; Oct. 26d. 12h., Jupiter 3° S. In addition to these conjunctions with the moon, Mercury is in conjunction with Saturn on Oct. 4d. 01h., Mercury 3·5° S., and Venus is in conjunction with Mars on Oct. 4d. 06h., Venus 0·03° S. Mercury, an evening star, is too close to the sun for observation. Venus is a morning star, rising at 3h. 15m., 4h. and 4h. 45m. on October 1, 15 and 31, respectively. The stellar magnitude of the planet is – 3·4, and the visible portion of the illuminated disk varies from 0·88 to 0·93. Mars, a morning star, rises about 3h. 20m. throughout October, moving from the constellation Leo into Virgo, and towards the end of the month it lies midway between β and η Virginis. Jupiter rises at 20h. 55m., 20h. 05m. and 19h. on October 1, 15 and 31, respectively, and is stationary on October 15, afterwards moving westward in the constellation Taurus. Saturn is too close to the sun for favourable observation and on October 23 is in conjunction with the sun. Occultations of stars brighter than magnitude 6 are as follows, observations being made at Greenwich: Oct. 2d. 4h. 12·5m., θ Canc. (*R*); and Oct. 24d. 19h. 54·6m., 36 Taur. (*R*), *R* referring to reappearance. On October 1 the planet Uranus, magnitude 5·9, occulted by the moon, reappears at 4h. 20·0m. The Orionid meteors, active from about October 20 to October 23, will not be easily observed owing to moonlight.

Announcements

H.R.H. THE DUKE OF EDINBURGH has accepted honorary fellowship of the Royal Aeronautical Society. The following have also been made honorary fellows of the Society: Sir Geoffrey de Havilland, Sir Arthur Gouge and Lord Hives.

THE Lord President of the Council has appointed Mr. W. L. Heywood, general secretary of the National Union of Dyers, Bleachers and Textile Workers, and secretary of the National Association of Unions in Textile Trades, to be a member of the Advisory Council for Scientific and Industrial Research.

THE Italian Society of Geophysics and Meteorology is offering a scholarship of 300,000 lire for the academic year 1953–54, which is intended to enable a student to complete his studies in meteorology or geophysics and is tenable at either the Institute of Terrestrial Physics of the University of Naples or the Institute of Geophysics and Geodetics of the University of Genoa. Details of application, which should be made before October 15, and further information can be obtained from the Society at Via Balbi 5, Genova.

THE thirtieth meeting of the Australian and New Zealand Association for the Advancement of Science will be held in Canberra during January 13–20, 1954, under the presidency of Sir Theodore Rigg, director of the Cawthron Institute, Nelson, New Zealand. The hon. secretary for this meeting will be Dr. C. Barnard, Box 109, City, Canberra.

THE Physical Society's thirty-eighth Annual Exhibition of Scientific Instruments and Apparatus will be held during April 8–13, 1954, in the Physics and Chemistry Departments of the Imperial College of Science and Technology, South Kensington, London, S.W.7. Further information can be obtained from the Secretary-Editor of the Physical Society, 1 Lowther Gardens, Prince Consort Road, London, S.W.7.

ARISING from the success of the short symposium on analytical chemistry held in Birmingham in 1952, the Midland Society for Analytical Chemistry will be holding a similar but larger symposium during August 25–September 1, 1954. Besides the presentation of original papers and discussions of recent advances in various analytical fields, there will be an exhibition of new and special apparatus, and visits to local places of interest will be organized. Further information can be obtained from the secretary of the symposium, Dr. J. W. Robinson, Post Office Engineering Department, Birmingham 9.

A CONFERENCE on "Field Studies in Urban Areas", suitable especially for teachers, will be held in the Anatomy Theatre, University College, Gower Street, London, W.C.1, on October 24. The conference is being organized by the Association of Agriculture and the Joint Biology Committee, the latter being made up of representatives of various teaching, biological and nursing bodies. The chairman of the conference will be Mr. F. H. C. Butler, director of the Council for the Promotion of Field Studies. Further information can be obtained from the Secretary, Joint Biology Committee, 11 Fillebrook Hall, Fillebrook Road, Leytonstone, London, E.11.

A SHORT summary of the views of Einstein, De Sitter, Friedmann, Eddington and others on the expanding universe is given by Paul Couderc in an article entitled "Les Théories de l'Universe en Expansion" (*l'Astronomie*, January 1953). The author holds the relativity theory of the expansion of the universe to be valid until proof to the contrary is forthcoming. The article is a useful synopsis of the author's more comprehensive treatment of the subject in "The Expansion of the Universe" (1952), translated by J. B. Sidgwick.

PLASTIC DEFORMATION OF METALS

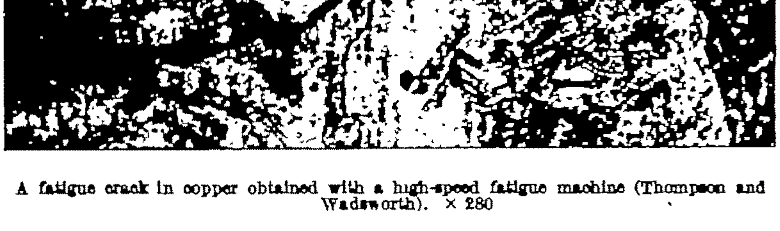
During July 15–16 a conference was held at the H. H. Wills Physical Laboratory of the University of Bristol on the plastic deformation of metals, with special reference to creep and fatigue. The conference was preceded during July 13–14 by a course of lectures by members of the staff of the Laboratory on recent developments in the theory of dislocations, especially on those which are relevant to the subject-matter of the conference. The course also included a review of the experimental evidence for the existence of dislocations. At the conference the following papers were given: D. McLean (National Physical Laboratory), a survey of recent work on creep; G. Masing (Göttingen), a survey of recent work in Göttingen on the deformation of metals; A. H. Cottrell (Birmingham), effect of twisting on the tensile strength of aluminium crystals; G. B. Greenough (Sheffield), residual strains in plastically deformed iron; J. Sawkill (Sheffield), deformation of gold crystals in pure shear; J. Nutting and G. Thomas (Cambridge), plastic deformation in two-phase alloys, and metallography of duplex slip; R. Cahn (Birmingham), some results on creep in zinc; A. G. Duce and G. C. Smith (Cambridge), surface markings in fatigue; J. W. Martin (Cambridge), fatigue of internally oxidized materials; A. K. Head (Melbourne and Bristol), the rate of spread of the fatigue crack; J. Clayton-Cave (British Iron and Steel Research Association, Sheffield), scatter of fatigue life; A. Deruyttere (Sheffield), cleavage fracture of zinc single crystals; C. E. Phillips (Mechanical Engineering Research Laboratory), a discussion of the size effect in fatigue; P. J. E. Forsyth (Royal Aircraft Establishment), a discussion of the work on fatigue at the Royal Aircraft Establishment, Farnborough.

After listening to the papers presented at this conference, it seemed to the present writer that, though we are beginning to understand the mechanism of plastic flow and work-hardening, the same cannot be said either of creep or of the various types of fracture. The discussion after McLean's able survey of creep showed that there was no agreement as to the rate-determining process. Both slip along the brain boundaries and deformation of the grains occur, and in principle either could control the rate. Those who maintained that it is the deformation of the grains with the accompanying cell formation or polygonization that matters had to explain how the grain size could affect creep-rate. One suggestion put forward was that, when the grain size is small, slip lines will frequently terminate on the grain boundaries, and that the annealing of the strains set up there would occur more rapidly, because of the ease of self-diffusion along the grain boundary.

Prof. Masing reported on the work of the Gottingen school on 'easy glide' of metal single crystals, on its dependence on orientation and on the surface markings which result. One fact which came out very clearly from his lecture was that, under conditions of easy glide in which slip on one system only occurs, deformation bands are formed. Deformation bands, with their accompanying X-ray asterisms, are therefore not directly related to work-hardening. Although the kinematics of their formation remains obscure, it is clear that they form a configuration of low energy in which dislocations can arrange themselves, and that dislocations trapped in this way are wasted so far as hardening is concerned. It seems that, in easy glide, dislocations either escape from the crystal or form deformation bands.

Turning now to fracture, there was considerable discussion of the work at the University of Sheffield on fracture of hexagonal metals, both single crystals and polycrystals. It was generally agreed that pre-existing Griffiths cracks are not the cause of fracture, but it was suggested that slip lines formed in the early stages of flow may act in a similar way. The stress around the end of a slip line is expected to be similar to that around the end of a crack, and thus to fall off with distance r from the end as $\sigma\sqrt{(l/r)}$, σ being the applied stress and l the length of the slip line. Just as, when the stress rises above a certain value, a Griffiths crack will extend, so, when the stress rises above a value of order $G\sqrt{(b/l)}$, we expect a crack to be initiated and to spread from the end of a slip line; b is here the interatomic distance. The linear relationship found at Sheffield between fracture stress and the reciprocal of the square root of the grain size suggests an explanation of this sort; if the stress exceeds a certain value, the first slip line formed crossing a grain breaks the specimen.

On the subject of fatigue, recent work at Melbourne, at the National Physical Laboratory, at Cambridge, and at Bristol on relatively pure non-ferrous metals revealed some measure of agreement as to what is observed. During the first thousand cycles or so the metal hardens and the area of the hysteresis loop greatly contracts, and towards the end of this process some slip lines appear. This occurs both with



A fatigue crack in copper obtained with a high-speed fatigue machine (Thompson and Wadsworth). × 280 the very slow machine developed at Bristol, taking several minutes for each cycle, and at frequencies of 1,000 c./s. Thereafter some of the slip lines broaden, according to Duce (Cambridge) these being those oriented in the direction of maximum shear stress. This goes on throughout the second stage of fatigue, which includes the bulk of the fatigue life. As regards the hysteresis loop, at Cambridge and at Melbourne it is found that its area remained constant during the second stage, whereas Thompson (Bristol) and the investigators at the National Physical Laboratory, working at different frequencies on the same copper, found a steady increase in the energy loss, together with the appearance of new slip lines. No obvious reason for the discrepancy was suggested. Also Thompson put forward results, confirming earlier work by Sinclair and Dolan[1], that frequent annealing does not increase the fatigue life of his copper specimens.

Head[2] (Melbourne) put forward a theory of the spread of a fatigue crack, obtained with many simplifying assumptions, but showing how, due to the work-hardening and subsequent fracture of the material just at the head of a crack, the slow growth of the crack might occur. He obtained the equation for the rate dc/dn per cycle at which the length c of the crack increases:

$$\frac{dc}{dn} = Ac^{3/2}; \qquad (1)$$

A is a constant which varies rapidly with stress and otherwise depends on such quantities as the rate of strain-hardening and the limit of ductility. He gave evidence to show that his equation is in reasonable agreement with experiment, at any rate for steels.

In view of the fact that damage which cannot be destroyed by annealing occurs early on, Head suggested that almost the whole fatigue life might be associated with the spread of a crack, and that equation (1) would account quantitatively for observed fatigue-lives if the crack were said to start from a length of 10^{-4} cm. On the other hand, Thompson showed some photographs of fatigue cracks in copper which suggest that initiation and spread of the crack are two separate processes. One of the photographs is shown in the illustration. It suggests that initiation involves the fracture of a single grain, in this case 10^{-2} cm. in width, and only after that does a crack spread by a mechanism as conceived by Head. As observed by several authors, cracks form in the heavily worked region of the broad slip lines. This, and the fact that early damage survives annealing, would suggest that the visible crack across a grain may result from a large number of small cracks which occur as the results of stress concentration at the ends of the slip lines in a single cluster.

No account can be given here of the various surface markings and cell structures which were discussed by contributors to the conference. Clearly the deformation of metals under alternating stress has many similarities to normal cold-work. An outstanding problem still remains, however, and that is why, over a significant range of stress, it takes as many as several million cycles to produce the effects observed.

---

BIOCHEMISTRY OF LIPIDS

A THREE-DAY colloquium on the "Biochemical Problems of Lipids", sponsored by the Royal Flemish Academy of Sciences, was held recently in Brussels under the presidency of Prof. R. Ruyssen, of Ghent. The meeting was formally opened by Prof. E. Polinard, president of the Academy. The scientific programme was divided into three main sessions—the first dealing with the chemistry and physics of lipids and technical methods; the second being concerned with the intestinal absorption of lipids; the third with lipid biosynthesis.

The opening speaker of the first session was H. A. Boekenoogen (Unilever Research Laboratories, Zwijndrecht), who reviewed the chemical characteristics and classification of the more important lipids. Some discussion arose on the use of the term 'lipid'; it was generally felt that the wide biochemical use of the word should be retained and that the more specific chemical names available for individual lipids should be used when precise particularization is needed. The methods of dispersion of lipids in an aqueous medium and some of the factors concerned were discussed on the basis of papers in this field presented by D. Dervichian (Institut Pasteur, Paris) and P. Ekwall (Åbo). The separation of fatty acids by chromatography provoked discussion on a number of technical points following a paper on this subject by J. Boldingh (Unilever Research Laboratories, Zwijndrecht). C. Hocking (Cambridge), in a paper with J. H. Schulman (Cambridge), presented evidence of a model system that promoted the passage of negatively charged lipid particles through membranes.

Detailed consideration of molecular structure was provided by the discussion on the contributions of E. Klenk (Cologne), who described the investigation of the structure of long-chain polyethenoid fatty acids, and J. N. Hawthorne (Birmingham), who gave an account of the work he had undertaken to establish the structure of inositol-containing phosphatides derived from the soya bean. The association between lipids and proteins in biological structure was opened up by J. B. Finean (Birmingham), who gave a paper on his X-ray diffraction studies on nerve myelin. By studying the effect of drying, tension and the action of solvents, he was able to present useful data on the ultra-structure of myelin in both peripheral and optic nerve. The importance of lipids in cell structure was the subject of further debate in connexion with the membrane of the red blood cell, the stability of which formed the basis of two papers—one by R. Ruyssen (Ghent) and the other by B. A. Pethica (Birmingham).

Discussions during the second day on the intestinal absorption of lipids can be conveniently considered in relation to the three phases of absorption—intraluminar, cellular and distributive. Consideration of the intraluminar phase of absorption was opened by W. F. R. Pover (Birmingham), who described experiments on lipolysis, fine emulsification and the distribution of lipids between the oil and water phase. He presented evidence to show that both *in vitro* and *in vivo* the hydrolysis of long-chain triglycerides is likely to be incomplete, that the glyceride residue would be finely dispersed to a particle size of less than 0·5 μ and that the long-chain fatty acids would be retained almost entirely in the oil phase, provided that the conditions approximated to those normally found in the upper small intestine. In contrast, tributyrin is rapidly hydrolysed, is not emulsified and the butyric acid formed is dispersed about equally between the oil and water phase. P. Desnuelle (Marseilles) gave an account of the extensive study by his group of the products of lipolysis under various conditions. The rate of hydrolysis of different glycerides varies, and the reasons for this were discussed. B. Borgström (Lund) claimed that there is considerable re-formation of glycerides and transesterification, so that all the fatty acids in the glyceride may have been detached at some time in the course of the reaction. He agreed, however, that intestinal absorption of glycerides could occur without complete hydrolysis. After discussion it was generally agreed that the basic concept of the Pflüger–Verzár hypothesis that complete hydrolysis of glycerides is an essential step in fat absorption is not correct.

Consideration of the cellular phase of fat absorption was begun by H. G. Sammons (Birmingham), who discussed the passage of lipids through the outer border of the intestinal cell. He presented the evidence for considering that the outer border of the intestinal cell has a canalicular structure and described experiments on the absorption of long-chain and short-chain glycerides, paraffin, castor oil and water-insoluble esters, all of which illustrated in various ways the close relationship between fine emulsification in the intestinal lumen and absorption of the water-insoluble glyceride fraction. Considerable discussion followed, both on the structure of the outer border of the intestinal cell and on particulate absorption. P. Favarger (Geneva) presented a paper on the relationships between the absorption of glycerides and sterols, which, he felt, introduce the necessity for some transport mechanism more specific than simple oil-solubility. It might be that particulate absorption only carries lipids to the bottom of the fine canals and at this point some selective carrier mechanism for sterols might come into action. There do not appear to be sufficient data available at present to resolve these problems.

Consideration of the distributive phase of absorption was introduced by A. C. Frazer (Birmingham), who described the almost quantitative recovery of long-chain glycerides from the chyle. This lipid is finely emulsified and gives rise to the classical alimentary systemic hyperlipæmia. In human subjects with no pancreatic lipase, as shown by intestinal intubation, no intraluminar emulsification and no alimentary hyperlipæmia occur. If a finely dispersed oil-in-water emulsion containing particles less than 0·5 μ in diameter is injected intraduodenally in such patients, a normal systemic hyperlipæmia occurs.

Certain lipids, however, are absorbed, but cannot be quantitatively recovered from the chyle. This has been observed in the case of short-chain fats and paraffins. These substances must either be metabolized in the intestinal cells or transported into the body by the alternative portal route. In the case of the shorter-chain fatty acids, transport in the portal vein has already been demonstrated, using decanoic acid labelled with carbon-14. The possibility of metabolic modification in the intestinal cell is an important consideration in the study of selective absorption. J. Fernandes, in collaboration with H. A. Weijers and J. H. Van de Kamer (Centraal Instituut voor Voedingsonderzoek, Utrecht), described studies carried out on a patient with a chylothorax. Long-chain fats were readily recovered from the chyle but short-chain fats were not. H. J. Thomasson (Unilever Research Laboratories, Zwijndrecht) described a new method for the biological assay of essential fatty acids.

The final session was opened by S. J. Folley (Reading), who described his classical work on the synthesis of lipids in mammary gland slices, with special reference to the influence of endocrine factors. J. Peeters (Ghent) continued with an account of his studies using the perfused udder. G. Popják (National Institute for Medical Research, London) presented the evidence for considering that fatty acids and cholesterol can be built up from 2-carbon fragments, and he described studies showing the synthesis of fatty acids from glucose labelled with carbon-14. R. Ruyssen (Ghent) described the incorporation of carbon-14 into fatty acids, and K. Bloch (Chicago) presented the evidence for the formation of cholesterol from squalene, and discussed the probable way in which this may occur. S. Bergstrom (Lund) gave an account of the methods he has developed for the detailed study of individual bile acids. K. Bernhard (Basle) described synthetic lipids containing triple bonds. This concluded the last scientific session.

The members of the colloquium decided to arrange future meetings from time to time, to discuss biochemical problems involving lipids. The Royal Flemish Academy of Sciences was thanked for its generous support, and the colloquium was formally closed by the president of the Academy. The full proceedings of the colloquium will be published in due course.

ANIMAL AND VEGETABLE RESOURCES OF GREAT BRITAIN

About five years ago suggestions were made to the Lord President's Office, in papers submitted by Dr. F. N. Woodward and Mr. A. N. Duckham, that more attention should be given in Britain to increasing the efficiency of the production and utilization of agricultural crops and other biological materials. Emphasis was placed upon possible uses for waste products, and it was pointed out that in the United States four regional laboratories had already been established for this purpose under the Bureau of Agricultural and Industrial Chemistry. Eventually, a team of three experts was chosen, made up of Dr. Woodward, Dr. A. B. Stewart and the late Mr. John Maxton, for the purpose of surveying all branches of industry concerned with biological, as distinct from mineral, products. The team proceeded to approach about two hundred individuals or organizations in the fields to be covered, including forty-two government departments, thirty-six research organizations, sixty-one industrial firms, twenty producers and manufacturers' organizations and twelve university departments. Its report, "A Survey of Agricultural, Forestry and Fishery Products in the United Kingdom and their Utilization", has recently been published under the auspices of the Development Commission[*].

More than formal tribute is due to the memory of Mr. John Maxton, who was director of the Institute of Agrarian Affairs in the University of Oxford, for his editorial skill in condensing vast masses of important information into a report which is concise, well arranged and pleasant to read. The subjects covered actually exceed the scope of the title in including imported agricultural crops which are processed in Britain, such as oil-bearing seeds, and also industrial biological products, such as malt, alcohol and antibiotics. Foodstuffs certainly predominate among the materials investigated, but attention is also given to non-edible products such as timber, leather, wool, cotton, paper and glue.

---

Agricultural crops. In Britain farmers grow only about one-third of the nation's wheat requirements, and nearly all the maize is imported. Almost all the barley and oats, however, are home grown. About half the barley is made into malt, and is used mainly for brewing and distilling; most of the rest is given to farm animals, which also receive nearly 80 per cent of the oats. The small quantity of home-grown rye is used for human consumption. The economical use of straw has attracted attention, and by predigestion with alkali its digestibility by animals has been increased. In the sugar beet industry the residual pulp left after the removal of the sugar has proved valuable as fodder, but an economical use for the foliage has still to be found. Pomace, left after pressing apples for making cider, is used both as fodder and as a source of pectin for the jam industry. Interesting regional differences are seen in the production of different vegetable crops in various parts of the country. Thus Ulster specializes in potatoes, Lincolnshire in peas and beans, and East Anglia in sugar beet. Peat is classified, perhaps rather strangely, as an agricultural crop; it contains about 12 per cent of wax which might be used for the manufacture of polishes and in electric cables. The imported crops which are processed in Britain include oil-bearing seeds, coffee, tea, cocoa, cotton, jute, hemp and tobacco.

Animal products. Milk is such an excellent food that it is wasteful, except when the production exceeds the demand, to use it other than in liquid form. It is satisfactory, therefore, that only 10 per cent of the output in Britain is used for making butter, cheese, dried milk and other products. In the meat industry little seems to be wasted, except quantities of blood which exceed the capacity of the processing plants. Whole dried blood is used as a fertilizer, and the separated albumin in making plywood and paint. Collections of organs and glands for the extraction of hormones and other medical products are now made on 85 per cent of the animals killed in government slaughter-houses. A valuable source of leather is lost because few pigs are flayed, because bacon and pork are best marketed with the skin intact. Wool fat is a rich source of various waxy alcohols and also of cholesterol, which is a valuable starting material for the synthesis of certain hormones and vitamin D_2. In the Bradford area no less than 8,500 tons of wool wax are recovered annually from the sewage; most of the wax is used on the railways as axle grease.

Biological products. The brewing industry, with all its ramifications, is based essentially on the culture of micro-organisms. It is estimated that 130,000 tons of carbon dioxide are given off annually in the course of brewing. The gas has several important industrial applications, but the supply far exceeds the demand. A more modern application of microbiology has been the production of antibiotics such as penicillin and streptomycin. The 'felt' formed by the micro-organisms is a rich source of vitamins of the B group. Starch is produced in Britain to the extent of 46,000 tons from maize, with only 2,100 tons from rice and 3,850 tons from wheat.

Timber. In Britain there is only 0·07 of an acre of forest per person as compared with 6·47 acres in Norway and 0·85 acre in Europe as a whole. The constant need to import timber, and the chronic scarcity of supplies, are therefore readily understandable. Steps are being taken to rebuild the stock of standing timber after the inroads made necessary by the Second World War. Although one cannot hope to satisfy current requirements, reserves may at least be accumulated against a future emergency. Most of the timber is located in Scotland. Attention is also being given to the efficient use of wood waste. Small pieces of wood and sawdust may be used to make hard-board, paper or briquettes for fire lighting. Vanillin may be manufactured from the sulphite liquor obtained in the manufacture of paper from wood. The liquor may also be fermented to give alcohol, yeast or other products.

Research and development. The report includes a useful list of the research institutions concerned in the production or efficient utilization of the materials which come within its scope. The absence or sparsity of the analytical data on many important products is stressed, and the collection of more adequate information is strongly urged. Another pressing need is the provision of more adequate facilities for investigating processes for industrial application on the 'pilot plant' scale. Only a few laboratories have any plant at all, and it is usually old-fashioned or even unserviceable. Practically no chemical engineers, moreover, are employed by the Department of Scientific and Industrial Research, and none by the Ministry of Agriculture and Fisheries or by the Agricultural Research Council.

The authors are to be congratulated for enabling research workers employed by these organizations, and others, to learn more of what is going on outside their own orbits of activity. The prosperity of Great Britain may largely depend on how far this widening and quickening of interest can be sustained and extended.

THOMAS MOORE

RESEARCH AND DEVELOPMENT AT NON-PROFIT INSTITUTIONS IN THE UNITED STATES[*]

A STUDY of the funds administered by United States Federal agencies for research and development at non-profit institutions during 1950–51 and 1951–52, which has recently been completed by the National Science Foundation, indicates the extent to which the Federal Government now sponsors research and development at such institutions, rather than conducting the work in its own laboratories. While in 1940 sponsored research and development accounted for less than 10 per cent of all government expenditure for this purpose, in 1952 it accounted for 75 per cent. According to the study, Federal agencies administered 338 million dollars for scientific research and development at non-profit institutions during 1951–52, compared with 294 million dollars during 1950–51. Such institutions received 16 per cent of all Federal research and development funds during 1950–51, but only 15 per cent during 1951–52. The distribution among administering agencies and receiving institutions, and the nature of the work sponsored, showed little variation between the two years.

---

[*] The National Science Foundation. Federal Funds for Science. 1: Federal Funds for Scientific Research and Development at Non-profit Institutions 1950–1951 and 1951–1952. Pp. vi+48. (Washington, D.C.: Government Printing Office, 1953.) 30 cents.

During 1951–52, seventeen agencies of the U.S. Government sponsored research and development at non-profit institutions; but four agencies administered 98 per cent of the funds. The Department of Defense administered 53 per cent, the Atomic Energy Commission 36 per cent, the Federal Security Agency 5 per cent, and the Department of Agriculture 4 per cent. In the Department of Defense, the Department of the Navy accounted for 36 per cent of the total, or 64 million dollars, compared with the 62 million dollars of the Department of the Air Force and 51 million dollars of the Department of the Army.

Of the 427 recipient institutions, 403 were located in the United States, Alaska, Hawaii and Puerto Rico, and 295 million dollars went to 225 educational institutions, while three special research organizations, namely, the Brookhaven National Laboratory and the Oak Ridge Institute of Nuclear Studies, both of which are sponsored by the Atomic Energy Commission and operated under the joint auspices of groups of universities, and the Rand Corporation, which is operated by an independent organization, are closely related to educational institutions. The independent research organizations, forty-eight of which receive Federal grants, are, with the exception of the special research centres formed at the request of the Government, the sole institutional group with the primary purpose of conducting scientific research and development. Almost half these organizations, which received 17 million dollars during 1951–52, have been established within the past twenty years, and during the two years for which data are available the number of such organizations participating in Federal sponsored research and development increased from forty-three to forty-eight. During 1951–52, twenty-four research centres, defined as research and development projects, administered by non-profit institutions for the Federal Government, received funds; and all but three were operated by educational institutions, 47 per cent of the funds that went to non-profit institutions (or 159 million dollars) being received by these centres mainly for defence work or work related to defence.

Funds for programmes devoted primarily to scientific research and development amounted to 58 million dollars, and the total funds for support of research and development are estimated at about 75 million dollars, or rather more than 20 per cent of the total. During 1951–52 applied research received 5·1 per cent of the funds, development activity 22·9 per cent, and basic research 21 per cent. Most of the funds were assigned for work in the physical sciences, biological sciences during 1951–52 receiving 19 per cent, social sciences 3 per cent, increase of research and development plant 6 per cent, and the remainder going to the physical sciences. Of the recipient institutions, 39 per cent were universities, 18 per cent being professional technical schools and the remainder liberal arts colleges. Federal grants for the support of agricultural experimental stations were about 12 million dollars, and accounted for about a quarter of the funds available to the stations.

ISOTOPIC SPIN SELECTION RULES

By Dr. D. H. WILKINSON
Cavendish Laboratory, Cambridge

Isotopic Spin

It has long been recognized that, in some sense or other, the neutron and proton may be regarded as alternative states of the same particle, distinguished, without any specific assumption about nuclear forces, by the value of the isotopic spin co-ordinate[1]. The isotopic spin of the individual nucleon, the projection of which on the z-axis is represented by the value of the isotopic spin co-ordinate, bears a strong formal resemblance to ordinary intrinsic spin; the isotopic spin operators are closely related to the Pauli spin matrices. The idea of alternative nucleon states is suggested by the near-identity of the masses of neutron and proton, by their mutual interconversions that take place in ordinary beta-decay, by the beta-decay of the free neutron[2] and by the supposed role of charged mesons in connexion with nuclear forces; more recently we may add the transmutation of one nucleon into the other in reactions such as $p + p = p + n + \pi^+$ or $p + p = d + \pi^+$ (ref. 3) and $p + \pi^- = n + \pi^0$ (ref. 4).

The isotopic spin formalism has been widely used from the early days for computations concerning *few*-body nuclear systems; here it introduces nothing new but it makes the calculations look neater. If, however, we do not simply regard isotopic spin as a formal means of distinguishing neutron from proton but are prepared to link the formalism with a specific assumption concerning nuclear forces, we obtain novel results that are of considerable importance for the classification of *many*-body nuclear systems and for understanding certain apparently capricious aspects of nuclear reactions; it is not clear how certain of these results could be obtained outside the isotopic spin formalism except perhaps in a very cumbersome fashion. The assumption that we must make is that the specifically nuclear forces (that is, after allowing for the Coulomb and electromagnetic interactions) are independent of charge; n–n, p–p and n–p forces are equal in corresponding states. The total isotopic spin T of the system, formed from the isotopic spins of the individual nucleons according to the usual rules for the addition of angular momenta[1,2], then becomes a good, or almost good, quantum number, and its conservation in certain circumstances together with the selection rules governing its behaviour in others become matters of great physical consequence; the behaviour of the component along the z-axis, $T_z = \frac{1}{2}(N-Z)$, is generally trivial. Although we are unable, in any simple physical sense, to say what isotopic spin is, it is clear that the $2T + 1$ members of the isotopic spin multiplet represented by the $2T + 1$ values of T_z are simply all the different chemical elements that we may make from a given nuclear wave-function by turning neutron into proton and *vice versa* without change of that wave function before a halt is called by the Pauli exclusion principle. States that appear only in the self-conjugate ($T_z = 0$) nucleus are then of $T = 0$; those that appear also in the neighbouring isobaric nuclei of $T_z = \pm 1$ are of $T = 1$ and so on. The self-conjugate nucleus has the most states; those of $T = 0$ cannot be transferred to the neighbouring isobars by conversion of neutron into proton and *vice versa*, since for them, but not for those of $T = 1$, the Pauli principle is opposed to this increase in the number of identical particles. We may think of these $2T + 1$ projections T_z of T as responding to the Coulomb perturbation in the same way as the $2J + 1$ projections of the ordinary spin J along the z-axis are shown up by the perturbation of a magnetic field.

A precise definition of isotopic spin may be given in terms of the symmetry properties of the nuclear wave function.

Independence of Charge

It is well known that the specifically nuclear forces are indeed, to a large degree, independent of charge[6]. The singlet scattering lengths of (the specifically nuclear) n–p and p–p interactions are closely the same, and the small difference may be susceptible of quantitative explanation in terms of the differing electromagnetic interactions[7]. The singlet effective ranges for n–p and p–p interactions are not very different, if at all[8]. Within the rather large limits of experimental error, the n–n singlet scattering length is the same as those for n–p and p–p interactions[9]. The familiar quantitative comparison of the level schemes of isobaric nuclei of odd mass shows rather generally the close equivalence of the n–n and p–p interactions[10,11] (including the many-body interactions); this is also displayed by a comparison of n–d and p–d scattering[12].

There is no experimental evidence that conflicts directly with this attractive and simple hypothesis of charge independence which may, in principle, receive a very simple theoretical explanation based on the meson field[13]; this, in turn, derives some support from the existence of the π-meson triplet showing apparently charge-independent interactions with single nucleons[4,14]. (Apparent violations of the hypothesis are seen in high-energy nucleon–nucleon scattering[15], but it is quite possible that these phenomena may be reconcilable with independence of charge[16]. Again, it may be argued that the slight difference in mass between neutral and charged π-mesons[17] shows that the specifically nuclear forces cannot be completely independent of charge, but this does not necessarily follow.)

Isotopic Spin Multiplets

If, then, we admit the independence of charge of the specifically nuclear forces, we must expect the $2T + 1$ members of a given isotopic spin multiplet to have the same spin and parity; if we allow for the Coulomb interaction and the neutron–proton mass difference, we must also expect that they will have the same mass. In particular, the ground-states of the two neighbouring isobars of a self-conjugate ($T_z = 0$) nucleus will be of $T = 1$ and of equal mass, the same as that of the first $T = 1$ state of the $T_z = 0$ nucleus (the ground-state of which is of $T = 0$). In order to test this experimentally, one must be able to identify the first $T = 1$ state of the $T_z = 0$ nucleus and to compute the differences of Coulomb energy between the three isobars. This is possible for the triplets ^{6}He—^{6}Li—(^{6}Be), ^{8}Li—^{8}Be—^{8}B, ^{10}Be—^{10}B—^{10}C, ^{12}B—^{12}C—^{12}N, ^{14}C—^{14}N—^{14}O and ^{16}N—^{16}O—(^{16}F). The computation of the Coulomb energy is very uncertain, but if we use the simplest possible model of a uniformly charged sphere of conventional radius we obtain the result shown in Table 1. The column labelled $T_z = 0$ shows the experimental excitation in MeV. of the first $T = 1$ level in the self-conjugate nucleus; the columns labelled $T_z = +1$ and $T_z = -1$ show the excitation at which this level is expected to appear in the self-conjugate nucleus from consideration of the masses of the ground-states of these neighbouring isobars; these masses are known to better than 100 keV. except where indicated, the uncertainty in mass then being transferred to the predicted excitation energy. The starred estimates are based on the masses of nuclei within 1 MeV. of instability against heavy-particle emission; the Coulomb correction is then particularly suspect. (The first successful comparison of this kind was made by Lauritsen[18].)

Table 1

Triplet	$T_z = +1$	$T_z = 0$	$T_z = -1$
^{6}He—^{6}Li—(^{6}Be)	4·0*	3·58	unstable
^{8}Li—^{8}Be—^{8}B	17·0	17·0	16·3 ± 0·3*
^{10}Be—^{10}B—^{10}C	1·9	1·74	2·0 ± 0·1
^{12}B—^{12}C—^{12}N	15·1	15·09	15·5 ± 0·1*
^{14}C—^{14}N—^{14}O	2·2	2·31	2·5 ± 0·1
^{16}N—^{16}O—(^{16}F)	12·7 ± 0·5*	12·51	unstable

The identification of these lowest $T = 1$ states in lithium-6, boron-10 and nitrogen-14 is almost certain, in beryllium-8 it is very probable, in carbon-12 probable, and in oxygen-16 rather unsure.

As yet no certain identifications of isotopic spin triplets corresponding to excited states of $T_z = \pm 1$ nuclei have been made, though tentative identification of the 3·37, 6·2 and 7·54 MeV. states of beryllium-10 may be made with the 5·16 (3·42), 7·48 (5·74) and 8·89 (7·15) MeV. states of boron-10, the 6·10 MeV. state of carbon-14 probably corresponds with the 8·06 (5·75) MeV. state of nitrogen-14, the 2·28 MeV. state of lithium-8 may well be partnered by the 19·18 (2·18) MeV. state of beryllium-8 and the 0·95 MeV. state of boron-12 by the 16·10 (1·01) MeV. state of carbon-12. (The energy in brackets is the height of the state above the first $T = 1$ state.) When virtual levels are involved, the Wigner–Thomas[11] shift must be taken into account; when this is done, the correspondence between these various excited states is good despite the fact that we have no real reason for expecting the Coulomb correction to be independent of the state of excitation.

If we bear in mind the extreme crudity, in these light nuclei, of our correction for the Coulomb energy, these data constitute strong evidence in favour of charge-independence and hence for the idea that T should tentatively be regarded as a good quantum number.

The Selection Rules

Heavy-particle reactions. If we admit T as a good quantum number, it must be conserved in heavy-particle reactions; this has some simple and immediate consequences: (i) if we form a nucleus in a well-defined excited state of isotopic spin T, it must break up in such a way that the vector sum of the isotopic spins of the resultant bodies is also T; for example, a state of $T = 1$ may not lead by alpha-particle emission to a state of $T = 0$ in the residual nucleus; (ii) if we carry out a reaction in which both incident and product particles are of $T = 0$ (for example, a (dd'), $(\alpha\alpha')$, $(d\alpha)$ or (αd) reaction) then the residual nucleus must be left in a state the isotopic spin of which is that of the target nucleus; for example, we may not excite a $T = 1$ state in a $T_z = 0$ nucleus by inelastic scattering of deuterons since the target nucleus is of $T = 0$. It has indeed been found that we do not excite by this means the 3·58 MeV. state of lithium-6[19], the 1·74 MeV. state of boron-10[20] nor the 2·31 MeV. state of nitrogen-14[19], which are all, following Table 1, of $T = 1$ (on independent evidence). We may similarly understand the failure of the 2·31 MeV. state of nitrogen-14 to appear in the reactions $^{16}O(d\alpha)^{14}N$ (ref. 21) and $^{14}N(\alpha\alpha')^{14}N$ (ref. 22) and be confident that, for example, the reaction $^{12}C(d\alpha)^{10}B$ will not readily leave boron-10 in the state at 1·74 MeV. The 8·89 MeV. state of boron-10 (probably $T = 1$, $J > 0$) leads by alpha-particle emission preferentially to the 3·58 MeV., $T = 1$ state of lithium-6 as may be expected[23]; no transitions are found to the two lower ($T = 0$) states of lithium-6. This aspect of isotopic spin conservation was stressed by Adair[24], who also pointed out that the cross-sections for competing nuclear reactions that lead alternatively to members of an isotopic spin multiplet should be closely related.

It is not likely that these selection rules will be of as wide interest if any of the particles involved in the reaction has odd mass, since states of $T = \frac{3}{2}$ are of considerable excitation in light nuclei and two particles of $T = \frac{1}{2}$ may give a resultant state of $T = 0$ or 1 (though if the reaction proceeds via a well-defined intermediate state the isotopic spin of that intermediate state must, of course, be conserved in its subsequent break-up).

Beta-decay. The isotopic spin selection rules on beta-decay were first considered by Wigner[25]: they are $\Delta T = 0$ (the transition must, in fact, be between members of the same isotopic spin multiplet) for Fermi, and $\Delta T = 0, \pm 1$ for Gamow–Teller selection rules. The distinction between these cases is not usually of practical interest in light nuclei since, as Christy has pointed out[26], when the isotopic spin changes by one unit so does the ordinary spin, and a transition without change of ordinary spin is also accomplished without change of isotopic spin.

Gamma-ray emission. Radicati[27] has remarked that the selection rule on any gamma-ray transition in any nucleus with the exception of electric dipole in a self-conjugate nucleus is also $\Delta T = 0, \pm 1$. (Radiative transitions, like beta-decay, are patently not independent of charge, so we should not expect isotopic spin to be of necessity conserved in them.) The chance of satisfactorily identifying, say, a state of $T = 2$ in a self-conjugate nucleus or one of $T = 3$ in a nucleus of $T_z = \pm 1$ appears to be rather remote, and so this rule and those on beta-decay are of but little practical interest. For electric dipole transitions in nuclei of $T_z = 0$, however, we have the important rule[27,28] $\Delta T = \pm 1$. This rule may be seen in operation in suppressing the transition from the (2 −) state at 5·11 MeV. in boron-10 to the (3 +) ground-state and the (1 +) states at 0·72 and 2·15 MeV.[29], that from the 6·91 MeV. (2 +) state of oxygen-16 to the (3 −) state at 6·14 MeV.[29,30], that from the 13·70 MeV. (2 −) state of neon-20 to the (2 +) state at 1·63 MeV.[31] and that from the 8·06 MeV. (1 −) state of nitrogen-14 to the (0 +) state at 2·31 MeV.[31]. The examples in boron-10, oxygen-16 and neon-20 are between states of $T = 0$; that in nitrogen-14 is between states of $T = 1$. It is unlikely that these transitions are missing on account of ordinary fluctuations in the electric dipole matrix element, since such fluctuations appear to be rather small in light nuclei[32]; that their absence is indeed due to the isotopic spin rule is made probable by the observation[33] that electric dipole transitions between states of $T = 1$ are in fact not forbidden in nuclei of $T_z = +1$.

Photodisintegration. Isotopic spin selection rules are potentially of great interest in certain photodisintegration reactions[33]. If we average over all gamma-ray energies, the principal contribution to the photodisintegration cross-section must come from electric dipole transitions[34]. When the target nucleus is self-conjugate, this cross-section cannot become large until we are able to excite states of $T = 1$ in the compound nucleus. This happens in all cases below the giant electric dipole resonances for (γp) and (γn) processes (at about 20 MeV. in light nuclei) and so is not of interest for them. But consider the situation if we are interested in $(\gamma\alpha)$ or (γd) processes: it is now not enough that the gamma-ray energy be sufficient to excite a $T = 1$ state in the compound nucleus, since such a state will not readily break up by deuteron or alpha-particle emission until there is enough energy available to leave the residual nucleus itself in a $T = 1$ state. Thus (γd) and $(\gamma\alpha)$ processes may be forbidden participation in the giant resonance, their cross-section rising at higher energy when a $T = 1$ state becomes available in the residual nucleus. This effect is dramatically seen[33,35] in the reaction $^{12}C(\gamma\alpha)^{8}Be$, which does not share the giant resonance at 22 MeV. in $^{12}C(\gamma n)^{11}C$ and $^{12}C(\gamma p)^{11}B$ because its Q-value is − 7·4 MeV. and so the first $T = 1$ state in beryllium-8 (at 17·0 MeV.) is inaccessible below a gamma-ray energy of about 25 MeV. Above 26 MeV. the cross-section for the $(\gamma\alpha)$ reaction does indeed rise—although the total cross-section is falling rapidly and has dropped to a small fraction of its peak value—and more than 95 per cent of the transitions lead by electric dipole absorption to a (2 +) state of beryllium-8 at 17·0 MeV. that must surely correspond to the ground-state of lithium-8 (see Table 1). That this 17·0 MeV. state is indeed of $T = 1$ is further suggested by the fact that its width against break-up into two alpha-particles is substantially less than 0·3 MeV. Similarly, the reaction $^{16}O(\gamma\alpha)^{12}C$ ($Q = -7·1$ MeV.) above 24·5 MeV. leaves carbon-12 predominantly in its lowest $T = 1$ states at about 16 MeV.[36], and when enough energy is left in the residual carbon-12 it in turn breaks up by alpha-particle emission to leave beryllium-8 predominantly in its $T = 1$ state at 17·0 MeV.

Purity of Isotopic Spin States

We have so far supposed T to be a good quantum number; but in fact this cannot be so if only on account of the Coulomb perturbation that will mix states of differing isotopic spin (the effect of the charge-dependent electromagnetic interactions is relatively slight and may be neglected). The many successes, quoted above, of the raw isotopic spin selection rules show that isotopic spin states are, in fact, fairly pure; but we must now inquire what degree of purity is to be expected, and to what degree these rules may be relied upon. We may write in first-order perturbation theory:

$$\psi = \psi(T) + \sum_{T'} \alpha_T(T')\psi(T'),$$

where $\psi(T)$ is the wave function appropriate to isotopic spin T and $\alpha_T(T')$ measures its contamination, in amplitude, by a state of isotopic spin T'. If the process we are considering is forbidden for our state principally of isotopic spin T but allowed to one of T', it will occur at a rate $\alpha_T^2(T')$ times that expected of it *a priori* with neglect of the isotopic spin rules.

Now consider only one contaminating state:

$$\alpha_T(T') = \frac{H^C_{T'T}}{E_T - E_{T'}},$$

where $H^C_{T'T}$ is the matrix element of the Coulomb perturbation between the states of T and T' the respective energies of which are E_T and $E_{T'}$ (they must, of course, have the same spin and parity). We may obtain a crude estimate of $\alpha_T(T')$ by noting that H will be measured in units of e^2 divided by e^2/mc^2, that is, a few tenths of a MeV., while $E_T - E_{T'}$ will be a few times the level spacing, that is, of order 10 MeV. for the lowest state of light nuclei. $\alpha_T(T')$ may then be expected to be of the order of a few per cent. This approach to the purity of isotopic spin states was made by Radicati[37], who computed $\alpha_T(T')$ for some specific examples on the basis of the shell model in L–S coupling and found values of $\alpha^2_T(T')$ ranging from $2{\cdot}5 \times 10^{-[illegible]}$ to $4 \times 10^{-[illegible]}$. We must, of course, expect that $\alpha_T(T')$ will increase with increasing excitation of the state considered, owing to the decreasing separation of the states of T and T'.

We must, then, expect the isotopic spin selection rules to be violated; if we test them severely enough the 'factor of discouragement' that they afford is measured by $\alpha_T^{-2}(T')$, which may be as much as 10^4 for the lowest states of certain light nuclei and approach unity at an excitation of perhaps 20 MeV., when the concept of isotopic spin will lose much of its significance.

We should also note that, even if T were a good quantum number, the selection rule on electric dipole transitions would not be strict. Gell-Mann and Telegdi[38] have pointed out that the matrix element is not zero for an electric dipole transition with $\Delta T = 0$ in a $T_z = 0$ nucleus, but is rather of order appropriate to a magnetic quadrupole transition[38]; the transition is not completely forbidden, but rather discouraged by a factor of order[38] $3 \times 10^6/E_\gamma^2$, where E_γ is the gamma-ray energy in MeV. Since this factor is still as large as 3×10^4 for $E_\gamma = 10$ MeV., this effect is unlikely to compete with isotopic spin impurity as the principal mechanism for the violation of the selection rule. (Of even less importance is the relaxation of the rule due to the differing masses of neutron and proton which would allow electric dipole emission to take place, but 10^6 to 10^7 times more slowly than in an uninhibited transition.)

It appears from this discussion of isotopic spin impurity that we may not apply the raw selection rules without consideration of the factor of discouragement that that application would imply, especially for states of high excitation where $\alpha^2_T(T')$ may be rather large. For example, consider a state of $T = 1$ that may decay by electric dipole emission to a $T = 0$ state or, so far as ordinary spin and parity are concerned, by alpha-particle emission to $T = 0$ states only. The raw selection rules suggest that gamma-rays should be emitted but not alpha-particles; however, the 'uninhibited' width for alpha-particle emission may well be 10^5 times greater than that for gamma-ray emission, and so alpha-particle emission will certainly remain the dominant mode even under the inhibition of the isotopic spin rule. Just such an example seems to be afforded[40] by the (1 −) state of oxygen-16 at 13·09 MeV. which decays five hundred times more readily by alpha-particle emission to $T = 0$ states of carbon-12 than by electric dipole radiation (of large radiative width) to the ground state of oxygen-16; this is probably a $T = 1$ state with a large value of $\alpha^2_1(0)$ such as we may reasonably expect at such high excitation.

Other examples of violation of the raw rules are afforded by the observed electric dipole transition from the 7·12 MeV. (1 −) state of $T = 0$ in oxygen-16 to the ground-state[29,30], by the formation of the 5·16 MeV. (2 +) state of $T = 1$ in boron-10 by the bombardment of lithium-6 with alpha-particles[29] and by the emission of alpha-particles to $T = 0$ states from the following probable $T = 1$ states: 17·0 MeV. in beryllium-8, 7·48 MeV. in boron-10, 15·09 and 16·10 MeV. in carbon-12, 12·51 MeV. in oxygen-16. The 7·48 MeV. state of boron-10 also probably emits deuterons to the ground-state of beryllium-8. From these various examples we may place limits on $\alpha^2_T(T')$ for several states. The results are summarized in Table 2 where, it must be emphasized, the estimates of $\alpha^2_T(T')$ are rather crude in many cases.

These values of $\alpha^2_T(T')$ are all consistent with what is expected of the Coulomb perturbation of a specifically nuclear interaction completely independent of

Table 2

Nucleus	Level	T	T'	Reaction	$\alpha^2_T(T')$	Status	Ref.

The excitations are in MeV.: status *A* means that the stated value of T is almost certain, status *B* means that it is probable only. The bracketed levels contribute together the stated impurity. In obtaining these estimates use has been made of the single-particle gamma-ray widths[38,39] and the Wigner limit for heavy particle emission[39]. (The figure for the impurity of the 7·12 MeV. state of oxygen-16 merely indicates the strength of the transition and neglects the magnetic quadrupole effect mentioned above; this effect is of itself, sufficient to produce the observed apparent violation of the isotopic spin selection rule even for $\alpha^2_0(1) = 0$.)

charge. It appears that Table 2, taken in conjunction with the evidence of the isotopic spin multiplets (see above and Table 1), supports the idea of independence of charge and suggests that the isotopic spin selection rules may be applied with confidence to states of light nuclei, although their limited power as reflected in the finite value of $\alpha^2_T(T')$ must always be borne in mind.

In this connexion it is interesting to note a suggestion of T. Lauritsen[46] that many well-defined states of high excitation in $T_z = 0$ nuclei that are capable of emitting energetic alpha-particles (say above an excitation of about 13 MeV. in neon-20, for example) may owe this definition to their being principally of $T = 1$ and therefore having alpha-particle widths about $\alpha_1^{-2}(0)$ times smaller than $T = 0$ states which may be so broad as to be unobserved.

Charge Parity

The whole of the foregoing discussion has been based on the notion of the *charge-independence* of nuclear forces which is indeed demanded if we accept the evidence of the masses of the isotopic spin multiplets. However, if we relax this postulate of charge-independence into one of *charge-symmetry*—suppose only that *n–n* and *p–p* forces are equal and ignore the relative magnitude of the *n–p* forces—interesting selection rules still emerge. The evidence for this less restrictive charge-symmetry is rather more extensive than that summarized above for charge-independence but is of the same quality. It is now clear that we may define, but in self-conjugate nuclei only, a new quantum number, charge parity[47], that is odd or even according to whether the nuclear wave-function does or does not change sign when all neutrons are changed into protons and *vice versa*. Within the more general framework of charge-independence, the charge parity operator is associated with a rotation about the *x* (or *y*) axis in isotopic spin space, and the charge parity itself is odd or even according as to whether *T* is odd or even. Kroll and Foldy[47] have pointed out that, if we limit ourselves to reactions of self-conjugate nuclei, consideration of charge parity alone, and hence charge-symmetry alone, suffices to reproduce most of the isotopic spin results discussed above that have much practical importance. The rules are that, in heavy-particle reactions, charge parity is conserved while in the emission of electric dipole radiation (only) charge parity must change.

All experimental results connected with selection rules so far available do in fact refer to self-conjugate nuclei with *T* less than 2, and so, taken in isolation, bear strictly only upon the problem of charge-symmetry. But the evidence of the isobaric multiplets is in itself sufficiently strong to encourage the adoption of the fuller hypothesis of charge-independence and the use of the language of isotopic spin, although the justification for this on the basis of selection rules alone should properly await the identification of states of higher isotopic spin.

Meson and High-energy Processes

The principal concern of this account has been with the effect of independence of charge in light nuclei; but it must be mentioned that it is also of great importance in discussing high-energy interactions of nucleons and simple systems[48] and in determining relationships between various processes involving meson scattering and production[49]. Owing to the existence of the apparently symmetrical π-meson triplet with strong coupling to the nucleus, it becomes sensible to regard the π-meson as of isotopic spin one.

A New Type of Helium Liquefier

TWENTY-FIVE years ago, one of us[1] suggested an 'external work' machine to be used for the liquefaction of the gases of low boiling point, in particular helium and hydrogen, in a process similar to that used by Claude for the liquefaction of air[2]. The essential feature of the suggestion was to replace the conventional cylinder and piston of the expansion engine by one constructed from an elastic metal bellows. Such a bellows engine would form a gas-tight unit which could be suspended in a vacuum for thermal insulation, and one would expect the engine to operate with a high degree of reversibility. Though it was experimentally verified at the time that metal bellows could be used at hydrogen temperatures, the design of an engine was not pursued because the problem of fatigue fracture seemed to require extensive development work.

Since then, Kapitza[3] has built a helium liquefier incorporating an expansion engine in which a loose-fitting piston allowed gas to escape and so provide lubrication. Several people have built liquefiers based on Kapitza's original work, and Collins[4], in particular, has developed this type of liquefier into a commercially produced machine which has contributed much to the widening of low-temperature research.

As we believed that a simpler and much less expensive liquefier could be built using the bellows principle, we began, about three years ago, the design of such a liquefier. Our early experiments[5] showed, fortunately, that the fatigue-life increases as the temperature decreases and that the low-temperature life of commercially available bellows was sufficient to warrant the construction of a liquefier. The liquefier has now been in operation for the past seven months, and this is a brief report of its design and performance.

We used a bellows of 7·7 cm. outer diameter, 4 cm. inner diameter and 5·4 cm. length with fifteen convolutions. It is hydraulically formed from brass, one end being closed. The other end of the bellows is fitted with a cup which houses the valves and displaces most of the internal volume when the bellows are completely compressed. The valve cup is suspended in the centre of a vacuum case on a thin-walled stainless-steel tube. The inlet gas forces the lower end of the bellows downward as it expands, thus allowing the use of a thin tension rod to transmit the motion to a mechanism at room temperature where the work is dissipated. The valves are also operated by tension rods. The engine normally runs at 2–3 cycles per sec. The life of the bellows under the present operating conditions of 5·5 atmospheres inlet pressure and the very considerable stroke of 2·7 cm. is about 5 × 10⁶ cycles.

The heat exchangers and the liquid helium container are housed in the vacuum case, which is surrounded by a glass Dewar vessel containing liquid air for pre-cooling the gas. Helium gas at 20 atmospheres is supplied at the rate of 15 cubic metres per hr. (N.T.P.): 70 per cent is reduced to 5·5 atmospheres for the engine supply, while the remainder, after being cooled by the expanded gas from the engine, enters a Joule–Thomson liquefying stage.

At present the liquefier produces 0·4 lit. of liquid helium per hr., consuming 1·2 lit. of liquid air. This liquefaction rate is not the optimum value, as the output of the engine is not fully utilized because of heat leaks and inefficiency in the heat exchangers. A second liquefier is being designed in which these defects will be remedied. Although some work is still needed to find the optimum operating conditions for the engine as well as the most suitable material for the bellows, we feel that the bellows liquefier is an attractive method of producing liquid helium and, in particular, that fatigue failure will not be a serious obstacle.

A detailed description of the apparatus will be published elsewhere in the near future.

Estimation of Heterogeneity from Diffusion Measurements

IN order to estimate heterogeneity of molecular weights (in proteins) from diffusion measurements, Charlwood[1] uses the relation

$$\sigma/D_{2,0} = \sqrt{\left\{\frac{\Sigma\alpha_i D_i^2}{\Sigma\alpha_i D_i} \Big/ \Sigma\alpha_i D_i - 1\right\}} = \sqrt{\{D_{4,2}/D_{2,0} - 1\}}, \tag{1}$$

where D_i is the diffusion constant for the weight fraction α_i (in the sense of probability density), and σ the standard deviation of D_i. In terms of the absolute moments, $m_i = \int_{-\infty}^{+\infty} |x|^i y \, dx$ of the refractive index gradient curve this becomes

$$\sigma/D_{2,0} = \sqrt{\left\{\frac{m_4 m_0}{3m_2} - 1\right\}}. \tag{1a}$$

Experimental measurements have led Charlwood to believe that in view of the unavoidable experimental and computational errors it seems unlikely that it will be possible to use $[D_{4,2}/D_{2,0} - 1]^{1/2}$ as an estimate of $\sigma/D_{2,0}$ when that quantity is very small, and he, therefore, suggests that in such cases there is no other choice but to fall back on the ratio of the lower moments $D_{2,0}/D_A = \Sigma\alpha_i D_i \Big/ \left[\frac{1}{\Sigma\alpha_i/\sqrt{D_i}}\right]^2$ as a *semi*-quantitative estimate of the heterogeneity. The use of the fundamental relation between the ratio of averages of different order and the standard deviation[2] is, however, not restricted to the ratio $D_{4,2}/D_{2,0}$, and it will be shown that it is possible to obtain from a knowledge of $D_{2,0}$ and D_A a *fully* quantitative estimate of heterogeneity, since the difference $D_{2,0} - D_A$ turns out to be a measure of the standard deviation of $\sqrt{D}$.

We first note that $\sqrt{D_A} = \frac{1}{\Sigma\alpha_i/\sqrt{D_i}}$ is the harmonic mean of the weight distribution of $\sqrt{D}$. We then write the standard deviation of $\sqrt{D}$ as

$$\sigma^2(\sqrt{D}) = \Sigma\alpha_i D_i - [\Sigma\alpha_i\sqrt{D_i}]^2. \qquad (2)$$

Since the harmonic mean is by necessity equal or smaller (according to whether the distribution curve is symmetrical or skew) than the arithmetic mean, substitution of $\frac{1}{\Sigma\alpha_i/\sqrt{D_i}}$ in place of $\Sigma\alpha_i\sqrt{D_i}$ leads to the inequality

$$\sigma^2(\sqrt{D}) < \Sigma\alpha_i D_i - \left[\frac{1}{\Sigma\alpha_i/\sqrt{D_i}}\right]^2 = D_{2,0} - D_A. \qquad (3)$$

In words: the difference between the weight mean and area mean of the diffusion constant represents an upper bound to the variance of the square root of the diffusion constant; and

$$\frac{\sigma^2(\sqrt{D})}{D_A} < D_{2,0}/D_A - 1. \qquad (3a)$$

In words: the ratio of weight to area mean minus unity represents an upper bound to the variance of the relative fluctuation of the square root of the diffusion constant. In terms of the moments of the refractive index gradient curve,

$$\frac{\sigma^2(\sqrt{D})}{D_A} < \frac{2\pi H^2 m_2}{m_0^3} - 1, \qquad (3b)$$

where H is the maximum height of the curve.

If we wish to test the correctness of formula (3) we can do so by means of the approximate relation applying under certain conditions between the standard deviation of a variate and that of its square root[3]:

$$\sigma^2(\sqrt{x}) = \frac{1}{4}\cdot\frac{\sigma^2(x)}{x} \qquad (4)$$

$$\text{or } \sigma(\sqrt{x}) = \frac{1}{2}\cdot\frac{\sigma(x)}{\sqrt{x}}, \qquad (4a)$$

where x is the arithmetic mean of the variate x.

In our case, where only an upper bound for $\sigma(\sqrt{x})$ is available, (4a) becomes

$$(D_{2,0} - D_A)^{1/2} > \frac{1}{2}\cdot\frac{\sigma(D)}{\sqrt{D_{2,0}}}. \qquad (4b)$$

The quantities in formula (4b) are for sucrose + glycine and bovine plasma + sucrose given in the accompanying table:

	$D_{2,0}$	$D_{2,0} - D_A$	$\sigma^2(D)$
(a) Sucrose and glycine	78·0	6·0	240·0
(b) Bovine plasma albumen + sucrose	35·1	14·3	446·0
	From Charlwood's Table 2.		Calculated by equation (1)*.

Substitution into (4b) gives:

$$(a)\quad 2\cdot45 > \frac{1}{2}\sqrt{\frac{240}{78}} = 0\cdot9$$

$$(b)\quad 3\cdot8 > \frac{1}{2}\cdot\sqrt{\frac{352}{35\cdot1}} = 1\cdot6$$

As predicted by (3), the quantity $(D_{2,0} - D_A)^{1/2}$ represents an upper bound to $\sigma(\sqrt{D})$, as estimated by (4).

The values of $\sigma(D)$ are here, of course, only used for the sake of the test, the purpose of this paper being to devise a measure of heterogeneity for cases where the value for $\sigma(D)$ obtained from (1) is unreliable. If, however, $\frac{\sigma(D)}{D_{2,0}}$ is not very small, the above relation, involving then reliable estimates of both $\sigma(\sqrt{D})$ and $\sigma(D)$, affords in the amount of inequality a measure of skewness of the distribution of D_i, provided (4) is suitable for the distribution in question.

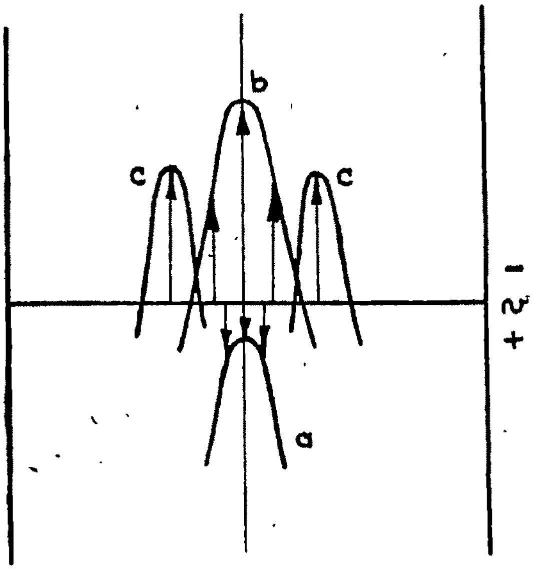
Axial Flow in a Vortex

A RECENT study of swirling fluid flow in a circular pipe has unexpectedly shown that reverse flow occurs in the centre of the pipe for some rates of swirl and discharge.

The experimental apparatus consisted of a 2½-in. inside diameter 'Perspex' pipe set vertically and surmounted by a cylindrical tank containing a ring of guide vanes which produced the swirl (free vortex). The rate of discharge was controlled by throttling at the lower end of the 56-in. length of pipe and by adjusting the inflow to maintain a constant free surface-level in the tank. Several different throttling devices were used, such as a circular orifice, a divergent cone terminating in a flat plate with an orifice, an annular orifice, etc. These were designed to give an average axial velocity of 1·5 ft./sec., $R = 3 \times 10^4$. The flow at $R = 1 \times 10^4$ was investigated with a smaller circular orifice. Dye was used for indicating fluid path lines but no quantitative velocity measurements were made.

At low rates of swirl the axial velocity at the pipe centre was less than the maximum as shown by curve *a*, in the figure. As the swirl was increased the axial velocity became negative at the centre (curve *b*), and finally, for higher rates of swirl, the axial velocity was positive at the centre but negative in a narrow region between the axis and the wall (curve *c*).

The type of throttling device determined the rate of swirl at which the transition from curve *a* to *b*



Reverse flow in a circular pipe with a vortex and curve *b* to *c* took place. It was possible to reproduce curve *c* with the circular and annular orifices only, and the transition from curve *b* to *c* occurred at a lower rate of swirl with the circular orifice. No qualitative change in the flow pattern could be seen between a point 8 in. above the outlet and the tank bottom, which was 6 in. below the inlet.

So far no satisfactory explanation of this phenomenon has been found. It seems to be related to the reverse flow at the centre of a Ranque–Hilsch vortex tube, although no thermal effects are present in this case.

These experiments were made in the Hydraulics Laboratory of the City and Guilds College, London, by permission of Prof. C. M. White.

Importance of Ion Exchange with the Solvent in Kinetic Studies

IN kinetic examination of nucleophilic substitution and elimination reactions with various attacking ions Y' in alcohol solution, Bunnett and Zahler[1] directed attention to complications likely to arise from the replacement of Y' by OEt′ consequent upon the equilibrium :

$$\text{(I)} \quad Y' + \text{HOEt} \rightleftharpoons \text{H}Y + \text{OEt}'.$$

In extension of our earlier work[2] on the effect of various nucleophilic reagents on the simultaneous substitution (II) and carbonyl elimination (III) reactions of organic esters of nitric acid, we have now obtained definite evidence of the great importance of such ion replacement reactions. We record below the separate values of the second-order velocity coefficients (in gm.mol.$^{-1}$ lit.sec.$^{-1}$) for the reactions :

$$\text{(II)} \quad Y' + \text{PhCH}_2\cdot\text{O}\cdot\text{NO}_2 \rightarrow \text{PhCH}_2Y + \text{NO}_3' \qquad (S_N2)$$

$$\text{and (III)} \quad Y' + \text{PhCH}_2.\text{O}.\text{NO}_2 \rightarrow \text{PhCH:O} + \text{H}Y + \text{NO}_2' \qquad (E_{CO}2)$$

for attack by *initially* added $Y' =$ OEt′, OH′ and OPh′ on benzyl nitrate in 100 per cent ethanol solution at 60·2°.

The nearly equal values (Nos. 1 and 2) of the velocity coefficients for OEt′ and OH′ suggest that actual attack is essentially by OEt′ in both experiments, in harmony with the independent findings of Caldin and Long[3].

With OPh′ (No. 3), the value of $kE_{CO}2$ exhibits a marked downward drift as the reaction proceeds. Such a drift should occur if the formation of free phenol in reaction (III) causes a gradual displacement of the equilibrium (I, Y' = OPh′) towards the left as the reaction proceeds. Initial addition of free phenol to the reaction mixture, in concentrations sufficient to swamp the small amount produced in reaction (III), should, by a mass law effect, cause more-or-less complete suppression of OEt′. The experimental value of $kE_{CO}2$ thus obtained should approach the true value for attack by phenoxide ion.

Exp. No.	Y'	Added HY	Initial concentrations		10^4k_2	
			[PhCH$_2$NO$_3$]	[Y']	S_N2	$E_{CO}2$
1	OEt′	—	0·0301	0·0366	96·7	1,350
2	OH′	—	0·0265	0·0406	99	1,440
3	OPh′	0·006 *M*	0·0493	0·0946	74·2	48·6 → 36·9*
4	OPh′	0·236 *M*	0·0524	0·1010	60·5	6·3 ± 0·09†
5	OPh′	0·322 *M*	0·0478	0·0897	61·4	5·3 ± 0·06†

* Coefficient drifts throughout run. † Coefficient constant thoughout run

It was found that such additions of free phenol in increasing concentrations (*a*) cause successive decreases in $kE_{CO}2$ towards an asymptotic value, and (*b*) gradually eliminate the drift in the constant. In the presence of 0·3 *M* phenol (No. 5) $kE_{CO}2$ has been reduced to about one-ninth of the original value and remains constant throughout the experiment. The true value of $10^4kE_{CO}2$ for OPh′ cannot, therefore, be greater than 5·3, and extrapolation suggests that it may be as low as 2–3. Within this range, however, the actual value makes no significant difference in the following deductions.

This value, together with that for ethoxide ion (No. 1), permits calculations of the changing concentration of OPh′ and OEt′ present throughout experiment No. 3. They reveal that, although [OPh′]/[OPh′] + [OEt′] = 0·97 → 0·98, because of the much greater nucleophilic power of OEt′, approximately 90 per cent of the total carbonyl elimination is effected by ethoxide ion. Even in experiment No. 5 it is still approximately 10 per cent. Incidentally, it will be noticed that the replacement of OEt′ by OPh′ has a much smaller effect on kS_N2 than on $kE_{CO}2$, in agreement with the well-known fact that, with decreasing basic strength, the nucleophilic power of the reagent towards hydrogen diminishes much more rapidly than it does towards carbon.

Our data also permit an approximate assessment of the value of the equilibrium constant K = [OEt′] [PhOH]/[OPh′] [EtOH] as $\sim 10^{-3}$.

The important implications of these conclusions on the validity of previously published results for attack of various nucleophilic ions in proton-donating solvents are obvious. Our investigations are being extended and will be published in full elsewhere when they are complete.

Equilibrium between Ethoxide and Hydroxide Ions in Ethanol

THERE is some evidence[1,2] that, in solutions made by dissolving sodium hydroxide in ethanol, much of the hydroxyl ion is replaced by ethoxide, the equilibrium $\text{OH}^- + \text{EtOH} \rightleftharpoons \text{OEt}^- + \text{H}_2\text{O}$ lying well to the right. We have confirmed this by measuring the equilibrium constant $K = [\text{OEt}^-][\text{H}_2\text{O}]/[\text{OH}^-][\text{EtOH}]$ at 25° C., using solutions made by dissolving sodium or sodium hydroxide in ethanol–water mixtures containing 10–50 per cent water by weight. The method adopted makes use of the fact that trinitrotoluene ionizes to give an intensely coloured ion in the presence of ethoxide[3].

The concentration of ethoxide ion in the solutions can thus be determined colorimetrically, and that of hydroxide ion can then be found by determining the total base concentration by titration.

The results show a regular trend with solvent composition (the activity coefficients have not been included in K); they can, however, be extrapolated to zero water concentration, whence we find that in pure ethanol $K = 0{\cdot}7 \pm 0{\cdot}2$. This implies that in a solution made by dissolving sodium or sodium hydroxide in ethanol containing x per cent water by weight, the percentage p of the base which is present as ethoxide ion is (if the concentration of base is not so large as to alter appreciably the percentage of water in the solvent) as follows:

x	0·2	0·5	1·0	2·0	per cent water
p	99	98	96	94	per cent ethoxide

These results are in agreement with the kinetic evidence of Baker and Neale[2], and also explain why the addition of water (1 per cent) has little effect on the rate or equilibrium of the reaction between ethoxide ion and trinitrotoluene or similar substances in ethanolic solution[4].

Mercuric Oxychloride as Tri-chlormercury-oxonium Chloride

LITTLE is known about the relations between the mercury and oxygen atoms in the crystal lattices of mercury compounds containing oxygen. We decided, therefore, to determine the structure of the most important representatives of this class of compounds by the use of the X-ray diffraction methods. We started our investigations with the study of the so-called mercury oxyhalides, among which the mercuric as well as the mercurous derivatives are known[1].

The crystal structure of these oxyhalides is of special interest. According to their chemical formulæ, it should contain components which, when alone, crystallize in lattices of an entirely different type. Consequently, the role of the oxygen atoms in the lattice of these compounds can scarcely be foreseen.

The present communication briefly reports the result of the X-ray analysis of the single crystal of an oxychloride quoted in the literature under the formula $2HgCl_2.HgO$.

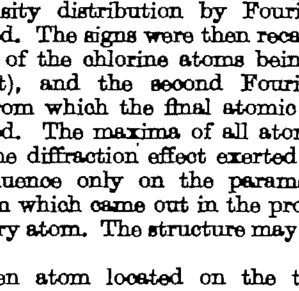
Its crystals belong to the cubic tetartohedral class. The unit cell edge is $a = 9{\cdot}22$ A. (thus we have confirmed the value $a = 9{\cdot}21$ A. obtained already by Gawrych[2] from the powder photographs). The space group is $T^4 - P2_13$, with four formula units in the elementary cell.

Copper $K\alpha$ radiation was used, and all possible $hk0$ reflexions were recorded with the help of a Weissenberg goniometer. The relative intensities were determined from the optical densities which had been measured with the use of a microphotometer. The absorption correction was carried out very carefully, since the absorption of X-rays in the crystal is very high ($\mu = 124$ mm.$^{-1}$). For this purpose, a prismatic shape was given to the specimen by grinding, and the absorption factors were calculated with the help of formulæ[3].

In the Patterson projection on the (001) many overlappings of the maxima occurred. Nevertheless, it was successfully interpreted by Bezjak's[4] modification of the vector algebraic method described by Lindqvist[5], and the preliminary co-ordinates of the mercury atoms were thus obtained. It followed that the mercury atoms are located in the general positions.

With the help of these mercury parameters, the signs of the structure amplitudes $F(hk0)$ were determined, neglecting the contribution of the chlorine and oxygen atoms, and the projection of electron density distribution by Fourier synthesis was computed. The signs were then recalculated (the contribution of the chlorine atoms being taken also into account), and the second Fourier synthesis evaluated, from which the final atomic co-ordinates were obtained. The maxima of all atoms were well resolved. The diffraction effect exerted a more pronounced influence only on the parameters of one chlorine atom which came out in the projection close to the mercury atom. The structure may be described as follows.

The oxygen atom located on the triad axis is surrounded by three mercury atoms in the same plane, the distance O—Hg being 2·03 A. On each mercury atom the chlorine atom is linked at a distance of 2·28 A. in such a manner that oxygen, mercury and chlorine atoms lie almost exactly in a straight line. The fourth chlorine atom is situated on the triad axis and is thus crystallographically different from the remaining three. The distance from the oxygen atom is 3·47 A., and from the two adjacent mercury atoms 2·94 A. and 3·13 A., respectively. Consequently, each oxygen atom has three such neighbouring chlorine atoms.



●, Mercury; ○, oxygen; ○, ○, chlorine

The different function of the chlorine atoms in this compound was already assumed by Lamure[6] from purely chemical considerations, but the structural formulæ proposed by him are inconsistent with the result of our investigation.

From the values of the interatomic distances, it follows that the $(ClHg)_3O$ group is to be considered as a complex cation, the anion being the chlorine atom in the special position. Mercury oxychloride $2HgCl_2.HgO$ is therefore in reality a tri-chlormercury-oxonium chloride $[(ClHg)_3O]Cl$. The detailed description of the structure with all atomic co-ordinates will be given elsewhere.

Obviously, this result gives us no right to assume that other mercury oxychlorides are also oxonium compounds, and further investigations in this field are in progress.

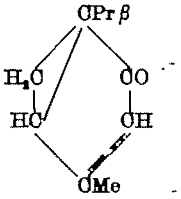
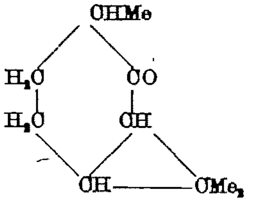
Some New Derivatives of Umbellulone

Semmler's structure (I) for umbellulone has been supported in recent years by the synthesis of some of its derivatives by Phillips, Ramage and Simonsen[1], Rydon[2] and Guha and Muthanna[3]. A useful review of this and other work has been given by Simonsen[4].



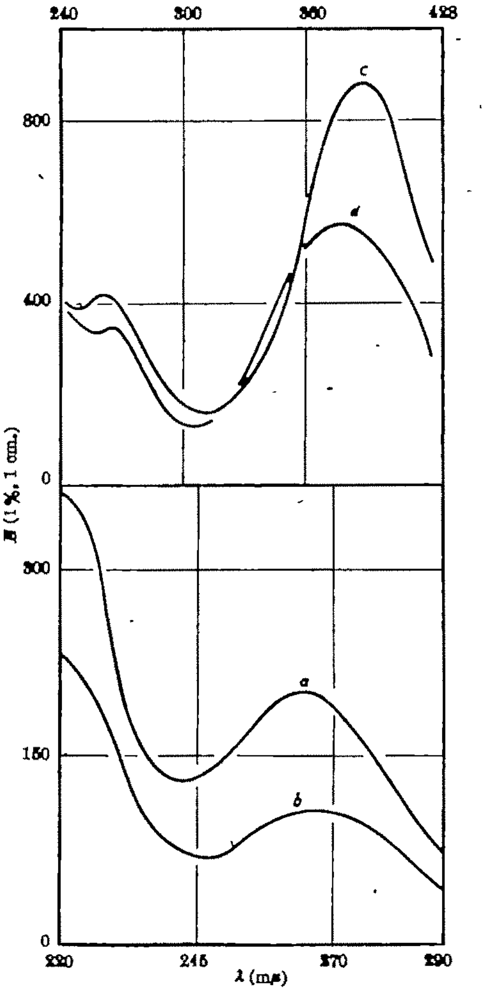
(I)



(II)

The absorption spectrum of umbellulone, however, is quite different from that of a simple α,β-unsaturated ketone (Gillam and West[5]), and exhibits two bands, each of fairly high intensity (see graph). The success of Gillam and his co-workers[6] in resolving the absorption spectrum of isocadinene into components by chromatography prompted the application of a similar technique to umbellulone.

A sample of the latter compound was prepared by fractional distillation from oil of Californian laurel, and was subjected to chromatography on an alumina column, using petroleum ether as developing solvent. Although the starting material was colourless, a faint yellow coloration (easily visible under ultra-violet light) developed in the column, and using this as guide, the extruded column was cut into portions, which were extracted by a mixture of petrol and alcohol. After removal of solvent, the fractions, consisting of oily material, amber in colour, and with a much less pronounced odour than the original oil, were examined spectroscopically. All gave the typical absorption spectrum of umbellulone, no significant variation in the ratio $\varepsilon(220)/\varepsilon(265)$ being observed. The intensity values found, however, were much lower than those of the starting material. On storing overnight in a vacuum desiccator, all except one of these fractions solidified to a mass of yellowish crystals. Recrystallization from petroleum ether yielded colourless crystals of an optically inactive substance, melting point 69° (found: C, 80; H, 9·8 per cent; $C_{10}H_{14}O$ requires: C, 80; H, 9·3 per cent), and gave the absorption spectrum shown in the graph ($\lambda_{max.}$(220) and 267 mμ, $E(1\%, 1 \text{ cm.})$ 238 and 107). The total yield of this substance, which was tentatively named ψ-umbellulone, was about 80 per cent of the starting material.



Absorption spectra of (a) umbellulone; (b) ψ-umbellulone; (c) 2,4-dinitrophenylhydrazone of umbellulone in chloroform; (d) 2,4-dinitrophenylhydrazone of ψ-umbellulone in chloroform

The chromatogram was repeated with development by ether and benzene respectively, elution in each case being by a mixture of alcohol and the developing solvent. Yields of ψ-umbellulone varying from 40 to 80 per cent were obtained, a pale yellow colour (brown under ultra-violet) appearing on the column in each case.

The 2,4-dinitrophenylhydrazones of both umbellulone and ψ-umbellulone were prepared. The former was slowly deposited from a mixture of umbellulone and Brady's reagent. Recrystallized from ethyl alcohol, in which it is appreciably soluble, it had a melting point of 134·5° (found: N, 16·9 per cent; $C_{16}H_{18}N_4O_4$ requires N, 16·9 per cent; in chloroform, $\lambda_{max.}$ 388 mμ, $E(1\%, 1 \text{ cm.})$ 888). The derivative of ψ-umbellulone was formed more readily, and in better yield. It was almost insoluble in ethyl alcohol. Recrystallized from chloroform, it had a melting point of 254–255° (decomp.) (found: N, 16·3 per cent; in chloroform, $\lambda_{max.}$ 379 mμ, $E(1\%, 1 \text{ cm.})$ 570). The absorption spectra of these two compounds are shown in the accompanying graph.

Hydrogenation products of both umbellulone and ψ-umbellulone were prepared by catalytic hydrogenation. β-Dihydroumbellulone was found to be, as described by previous workers, a mobile liquid with a camphor-like smell. Examined spectroscopically, it had $\lambda\lambda_{max.}$ (220) and 280 mμ, $E(1\%, 1\text{ cm.})$ 36·3 and 3·7. ψ-Umbellulone took up 1·0 mole of hydrogen per molecular weight of umbellulone, and formed a substance which crystallized in silky needles of melting point 79°; $\lambda\lambda_{max.}$ (220) and 280 mμ, $E(1\%, 1\text{ cm.})$ 23·9 and 1·5.

The similarity of the absorption spectra of umbellulone and ψ-umbellulone points to the presence of the same chromophoric system in both compounds. Koch[7] showed that *cis-trans*-isomers characteristically give rise to absorption spectra with only slight differences in the location of the bands, but appreciable differences in the corresponding extinction coefficients. Inspection of structure (I), however, shows that isomerization of this type cannot occur. It is interesting that two different β-dihydroumbellulols have been reported in the literature, that prepared by Semmler[8] being a liquid with boiling point 88–92°/10 mm., while Weinhaus and Todenhofer (1929) obtained a crystalline solid of melting point 55–56°. The relationship of the two substances has not been elucidated.

The absorption spectrum of carone (II) has been reported by Klotz[9], who found $\lambda\lambda_{max.}$ (200) and 288 mμ, ε 2,700 and 34. If Semmler's structure for umbellulone is correct, a similarity in the absorption spectra of carone and β-dihydroumbellulone would be expected, and was in fact found, the *K*-band of the latter compound; however, having a lower intensity, measured at 220 mμ.

The investigations were interrupted by the death of Dr. Gillam and were incomplete.

All melting points are uncorrected. Absorption spectra were measured on a Hilger E_3 quartz spectrograph, with a Spekker photometer, and unless otherwise stated are in ethyl alcohol solution.

Effect of Pyrophosphate on the Shortening of Muscle-Fibre Models in Presence of Adenosine Triphosphate

WEBER[1] has shown that pyrophosphate in fairly high concentrations (20 mM or above) produces relaxation in single glycerinated muscle fibres which have shortened or developed tension in adenosine triphosphate. He found, however, that it had this effect only when adenosine triphosphate was absent, shortening proceeding normally in presence of the latter. This contrasts markedly with the lengthening effect of the so-called Marsh factor, which is a protein found in aqueous extracts of muscle[2,3]. The latter effect manifests itself only in the presence of adenosine triphosphate and magnesium chloride (2–8 mM) and is inhibited[2,4] by traces of calcium chloride (0·2 mM).

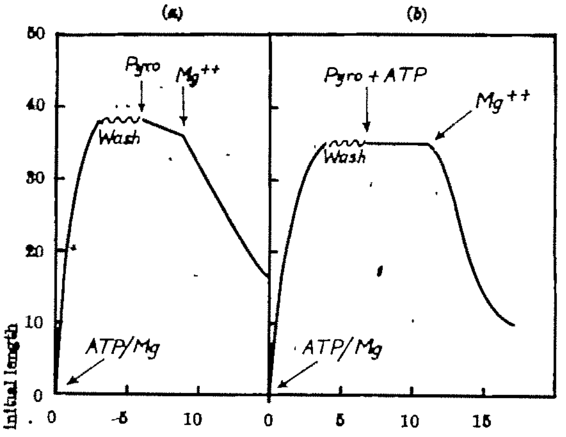

Fig. 1

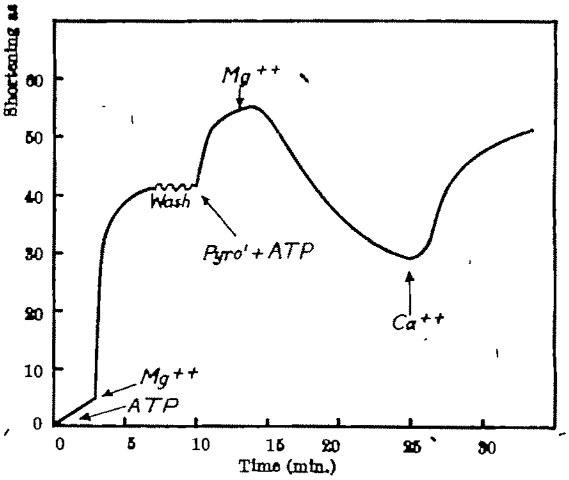

Fig. 2

Fig. 1. Effect of addition of 20 mM pyrophosphate to a muscle shortened under load in adenosine triphosphate/magnesium solution, (*a*) alone and (*b*) in the presence of 7 mM adenosine triphosphate, with and without magnesium chloride. ATP/Mg = 7 mM adenosine triphosphate + 4 mM magnesium chloride in 0·16 M potassium chloride; Pyro = addition of pyrophosphate to 20 mM; Pyro + ATP = addition of pyrophosphate to 20 mM and adenosine triphosphate to 7 mM; Mg++ = addition of magnesium chloride to 4 mM; Wash = wash for 10 min. in 0·16 M potassium chloride

Fig. 2. Effect of addition of 4 mM pyrophosphate and adenosine triphosphate to a shortened muscle, with and without magnesium chloride. Inhibition of lengthening by calcium chloride. Pyro' + ATP = addition of pyrophosphate to 4 mM and adenosine triphosphate to 7 mM; Ca++ = addition of calcium chloride to 0·2 mM. Other legends as in Fig. 1

In view of this, it was thought of interest to study the effect of magnesium and calcium ions and of adenosine triphosphate on lengthening in pyrophosphate. For this purpose glycerinated fibre-bundles, 0·35 mm. in diameter and 1·5–2·0 cm. long, were prepared by the method described by me[5]. They were loaded at 200–300 gm./sq. cm. and, after washing in 0·16M potassium chloride for 1 hr. to remove Marsh factor, shortened by at least 32 per cent of their initial length in the presence of 7 mM adenosine triphosphate + 4 mM magnesium chloride in 0·16 M potassium chloride (this solution is referred to as ATP/Mg). In the experiments which follow, all additions of substrates were made such that the final concentration of potassium chloride was 0·16 M.

The first experiment (Fig. 1,*a*) was designed to show the effect of 20 mM pyrophosphate (pH 7·0) on a muscle shortened previously by 38 per cent of its initial length in ATP/Mg and then washed to remove magnesium ions. It is seen that the pyrophosphate brings about slow lengthening which is accelerated five-fold by addition of magnesium chloride to 4 m*M*. The second experiment (Fig. 1,*b*) shows the effect of addition of 20 m*M* pyrophosphate + 7 m*M* adenosine triphosphate to a similar muscle. In this case, the muscle remained at its shortened length until magnesium chloride was added to 4 m*M*, when rapid lengthening set in. Thus magnesium chloride drastically modifies the effect of pyrophosphate with or without addition of adenosine triphosphate, and stimulates lengthening in both cases. The effect of the magnesium ion here is the opposite of its effect in the absence of pyrophosphate, when it markedly accelerates shortening, as seen at the beginning of the third experiment (Fig. 2). This experiment also illustrates the effect of adding pyrophosphate at 4 m*M*, that is, one-fifth the concentration employed by Weber. Here 7 m*M* adenosine triphosphate + 4 m*M* pyrophosphate brought about shortening which was rapidly reversed by addition of magnesium chloride to 4 m*M*. This lengthening was, however, immediately inhibited and shortening once more accelerated by addition of calcium chloride to 0·2 m*M*. In this connexion, it should be noted that calcium chloride in these low concentrations does not stimulate shortening in the absence of magnesium chloride, nor in its presence alone, but does so only when lengthening in pyrophosphate or Marsh factor has occurred.

Fig. 3 shows the effect of pyrophosphate concentration on the rate of lengthening (*a*) by itself, (*b*) in the presence of 4 m*M* magnesium chloride, and (*c*) in the presence of 4 m*M* magnesium chloride and 7 m*M* adenosine triphosphate. It is seen that lengthening occurs at pyrophosphate concentrations as low as 1 m*M* when the magnesium ion is present, whereas in its absence lengthening is not detectable at even 4 m*M* pyrophosphate. The addition of adenosine triphosphate as well as magnesium chloride further enhances the effect, although adenosine triphosphate in the absence of magnesium chloride brings about little or no change of length.

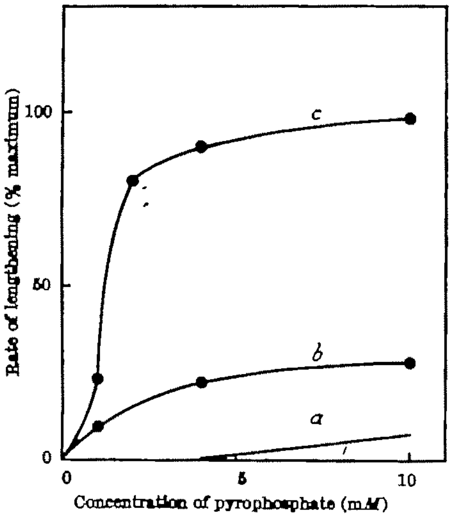

Fig. 3. Effect of pyrophosphate concentration on the rate of lengthening (*a*) by itself, (*b*) with 4 m*M* magnesium chloride, (*c*) with 4 m*M* magnesium chloride and 7 m*M* adenosine triphosphate. The rate is expressed as the percentage of the rate in 20 m*M* pyrophosphate per 4 m*M* magnesium chloride per 7 m*M* adenosine triphosphate (that is, the maximum value)

Thus, the effect of magnesium chloride on lengthening in pyrophosphate is strikingly similar to its effect when the Marsh factor is present. A further similarity is the effect of low concentrations of calcium chloride (0·2 m*M*) which reverses lengthening in both cases. It is not suggested, however, that pyrophosphate plays any part in the Marsh effect, but rather that, where lengthening is concerned, certain ionic conditions are common and necessary to whatever agent may be used to initiate it, and that, in particular, the presence of the magnesium ion (2–8 m*M*) is essential.

The work described in this paper was carried out as part of the programme of the Food Investigation Organization of the Department of Scientific and Industrial Research.

Glycerophosphoryl Choline as a Precursor of Free Choline in Mammalian Semen

In earlier studies it has been shown[1,2] that the very considerable concentration of choline in human semen (200–300 mgm./100 gm.) arises through the enzymatic hydrolysis by the prostate phosphatase of phosphoryl choline formed in the vesicular glands. In continuation of this investigation a method was worked out for the quantitative estimation of phosphoryl choline in tissue samples[3]. Choline is determined before and after treatment with phosphomonoesterase under optimal conditions. Purified prostate phosphatase is very useful for this purpose as it displays no activity towards secondary phosphate esters. On samples of tissue weighing 0·5 gm. it is possible to estimate amounts of phosphoryl choline corresponding to 10 mgm. choline chloride per 100 gm. of tissue with reasonable accuracy (± 5 per cent).

Analyses of accessory sex glands from the rat, guinea pig and rabbit revealed definitely the presence of phosphoryl choline in some of the glands (see accompanying table). When, however, a saline extract from the ventral prostate of the rat was mixed with extracts from the seminal vesicles or the dorsal prostate and incubated at 37° C. for one hour, much larger amounts of free choline were liberated than could be accounted for as phosphoryl choline, indicating the presence of some other precursor. Application of the method of Schmidt *et al.*[4] for estimating glycerophosphoryl choline revealed in the vesicular gland and the dorsal prostate of the rat a high concentration of a secondary choline phosphate ester, presumably glycerophosphoryl choline. The figure found for the seminal vesicle of the guinea pig is in good agreement with the figure of Kahane and Lévy[5] for total water-soluble choline.

The following procedure was employed in an attempt to identify the substance. A trichloracetic acid extract of vesicular glands from a number (4–8) of rats was extracted with ethyl ether three times, neutralized, and precipitated with barium acetate plus four volumes of ethanol. The clear alcoholic

WATER-SOLUBLE CHOLINE COMPOUNDS IN SOME ACCESSORY SEX GLANDS EXPRESSED AS MGM. CHOLINE CHLORIDE PER 100 GM. OF MOIST TISSUE

	Free choline	Phosphoryl choline	Glycero-phosphoryl choline
Rat (5 experiments)			
Vesicular glands	1–3	19–24	207–305
Dorsal prostate	2·5–9	8–13	56–98
Guinea pig (3 experiments)			
Vesicular glands	9–16	4	70
'Prostate'	2–5·5	2–8	0–12
Rabbit (1 experiment)			
Vesicular gland	1·4	2·8	49
'Prostate'	4	?	18

solution obtained after centrifugation was concentrated *in vacuo*, and barium removed as sulphate. The resulting solution showed a ratio of 1 : 1 between total phosphorus and 'bound choline'. 'Bound choline' was calculated as the sum of choline liberated by phosphatase and easily hydrolysable choline, which is liberated in 20 min. at 100° C. in *N* HCl. Treatment under these conditions for forty minutes does not increase the amount of choline formed. In alcoholic solution the substance gives a precipitate with cadmium chloride just like glycerophosphoryl choline.

After acid hydrolysis for 20 min. all the phosphorus is recovered in the fraction of barium salts soluble in water but insoluble in alcohol, and can be transformed quantitatively into inorganic phosphorus through the action of prostate phosphatase. This primary ester on treatment with periodic acid[6] behaves as a mixture of alpha and beta glycerophosphate. The acid treatment has possibly caused some alpha–beta migration[7].

The glycerophosphoryl choline is predominantly formed in the vesicular glands in the three species investigated and is apparently split very readily by an enzyme from the other accessory sex glands, especially the ventral prostate (rat) with liberation of choline. The formation of this substance appears to be under hormonal control as the level (on a moist tissue basis) drops to about 5 per cent of the normal level after castration (two months). The fact that choline is formed by different routes in semen of various animals certainly suggests that this substance is of importance in the reproductive process. The study of this problem is in progress.

This investigation has been aided by grants from the Jane Coffin Childs Memorial Fund for Medical Research, and Kong Christian den Tiendes Fond. It is hoped to publish a full report shortly.

Note. After this communication was submitted for publication a note by Diament, Kahane and Lévy[8] has come to my notice, in which the identification of glycerophosphoryl choline in rat seminal vesicles was performed as a ferric chloride complex.

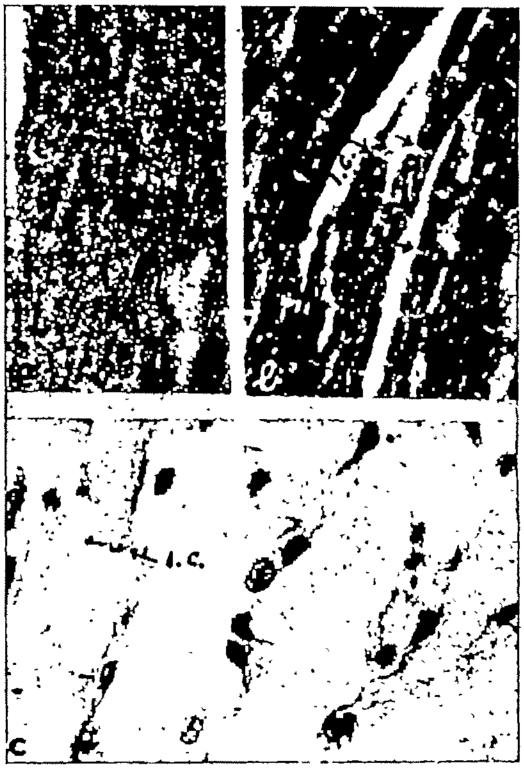
Enzymes of the Intercalated Disks of Heart Muscle Fibres

HEART muscle fibres are interrupted periodically by basophilic structures known as intercalated disks. They are stated not to occur in human fœtal heart muscle; but they have been recorded in that of other fœtal mammals[1,2] and of new-born humans[3]. Some of these authors claim that the disks increase in number with age. The function of these disks is undecided; they are invariably associated with the *Z*-band, and it is certain now that they are not, as was first thought, histological artefacts. They appear to be made up of parallel rods which are continuous at either end with the myofibrils. Among the suggestions made for their function (see Cohn, 1932 [4]) are that they may represent growing-points of cardiac muscle or that they may represent tendinous regions. There is no real evidence to support either of these suggestions.

When histochemical tests for succinic dehydrogenase are applied to heart muscle of the rat using the method described originally by Seligman and Rutenberg[5], but using neotetrazolium instead of blue tetrazolium as recommended by Shelton and Schneider[6], it can be seen that the intercalated disks show a positive reaction, thus indicating that they possess considerable metabolic activity. However, this reaction is a little less than that of the rest of the muscle fibre, so that in such preparations the disks can be distinguished but in most cases only with difficulty (Fig. *a*). However, if the succinic dehydrogenase reaction is applied to



(*a*) Succinic dehydrogenase reaction in normal rat heart muscle. Intercalated disks cannot be distinguished. (× 380.) (*b*) Succinic dehydrogenase reaction in heart muscle of normal rat treated with cortisone. Note intensification of reaction in fibres but negative reaction in intercalated disks. (× 380.) (*c*) Localization of enzyme hydrolysing riboflavin phosphate in intercalated disks and capillary endothelial nuclei in heart muscle of normal rat. (× 400) the heart muscle of rats which have been treated with cortisone, or deoxycorticosterone, the reaction in the muscle fibres is found to be increased but that of the intercalated disks to have become completely negative (Fig. *b*). Adrenalectomy results in a loss of activity from the fibres and disks, and treatment with cortisone restores the reaction completely in the fibres but the reaction is still negative in the disks. (Full details of this work are to be published elsewhere[7].)

Histochemical tests for phosphatases have also been carried out on heart muscle using modifications of the method first described by Gomori[8]. Non-specific alkaline phosphatase (using glycerophosphate as a substrate at pH 9·0) was found to be localized in the capillary vessels and in all the intercalated disks. Using a variety of sugar phosphates (which are also split by non-specific phosphatase) the same result was obtained. Adrenalectomy caused reduction of the phosphatase reaction in the intercalated disks but not in the capillaries. Injection of cortisone into intact animals had little effect.

Using riboflavin-phosphate as a substrate (at pH 9·0) scarcely any reaction was given by the capillaries or by the muscle fibres; but the intercalated disks were positive (Fig. *c*). With pyridoxal phosphate as a substrate the disks give a less-marked reaction than the fibres and some were completely negative. (This negative reaction, incidentally, suggests that the positive reaction given by the disks with other phosphate substrates was not due to an affinity by the disks for the reaction product, calcium phosphate.)

When riboflavin phosphate and pyridoxal phosphate were used as substrates in an acid medium (pH 5·0) heart muscle was completely negative with the former; but with the latter the sarcosomes gave a positive reaction, and in the intercalated disks there was a central very thin positive region surrounded on either side by a negative region.

I am indebted to Dr. H. A. Malaty for permission to refer to joint experiments on succinic dehydrogenase still in the press, and to Dr. A. L. Morrison director of research, Roche Products, Ltd., for a supply of vitamin phosphates.

Note added in proof, August 31. Dephosphorylating enzymes are frequently found in cellular sites where the production of free energy is necessary (for example, brush borders of absorbing cells), and the localization of these enzymes in the intercalated disks suggests that they may likewise be regions where release of energy takes place. Heart muscle fibres are not individually innervated as are those of skeletal muscle, and the contraction wave must spread from the regions of innervation through the cardiac syncytium. Because of the presence of dephosphorylating enzymes in the intercalated disks, it seems possible that the latter may act as boosters of this contraction wave. It is of interest that specific choline esterase preparations prepared according to the method of Ravin *et al.*[9] show, as did their preparations, that this enzyme is distributed in granular form throughout the cardiac muscle fibres and is not localized in the intercalated disks.

The effect of adrenalectomy on the enzyme reactions is not unexpected, but the effect of injection of cortisone and deoxycorticosterone into intact animals on the succinic dehydrogenase reaction of the disks, is difficult to explain. That this negative reaction by the disks may be a normal 'stress' effect is suggested by the fact that it was obtained in the heart muscle (obtained within an hour of death) of a man subjected to great and prolonged emotional strain prior to death.

Mode of Action of Beryllium on Alkaline Phosphatase

RECENTLY, Klemperer *et al.*[1] and Grier *et al.*[2] demonstrated the inhibitory effect of low concentrations of beryllium salts on alkaline phosphatase *in vitro*. This action was found to be rather specific[3] and we hoped to be able to shed new light on the old controversy concerning intestinal sugar absorption[4,5] and the role of alkaline phosphatase. Into isolated parts of the rat's small intestine, left *in situ*, we introduced solutions of glucose with or without added beryllium sulphate. There was no difference in the rate of absorption of glucose. Any conclusion from these experiments, however, is dependent on whether the phosphatase is inhibited *in vivo* as it is *in vitro*. Klemperer[3] suggested that interference with phosphatase action is related to the toxicity of beryllium. This would include an action on phosphatase *in vivo*. It seemed necessary, however, to obtain more conclusive evidence about this problem, especially about the mode of action of beryllium salts on alkaline phosphatase. Klemperer *et al.*[1] and Grier *et al.*[2] considered the possibility that, owing to the amphoteric properties of beryllium hydroxide, beryllate ions might be the inhibiting agent at the pH of optimal enzyme activity. We confirmed the observation of the first-named authors that the relative inhibition increases with increasing pH, reaching a constant high value at the pH of optimal enzyme activity; but we must agree with them that no conclusion can be drawn therefrom as to the form in which beryllium is active as an inhibitor. Treadwell and Boner[6], however, clearly demonstrated that beryllate ions do not exist at a pH lower than 12·5. At the pH of optimal enzyme activity (9·6) practically all the beryllium will be in the form of precipitated (colloidal) beryllium hydroxide.

We investigated the mode of action of beryllium in the following way. Phosphatase activity was determined by a modification (unpublished) of the method of Kroon *et al.*[7]. The reaction mixture consisted of 0·5 ml. buffer (barbital–hydrogen chloride), 0·1 ml. enzyme solution (normal tissue extracts as well as dialysed (phosphate-free) and purified enzyme solutions were used), 0·1 ml. substrate solution (= 4 mgm. sodium-β-glycerophosphate), 0·1 ml. water or beryllium chloride solution 8×10^{-4} *M*, final pH 9·6.

Experiments 1 and 2 in the accompanying table are, respectively, a control and a determination of the normal inhibition. Experiment 3 shows that the inhibiting form of beryllium is eliminated by filtration. This is not caused by adsorption on the filter

No.	Experiment	μgm. P liberated in 1 hr. at 37° C.	Inhibition (per cent)
1	Enzyme + buffer + water + substrate } incubated	14·2	—
2	Enzyme + buffer + BeCl$_2$ + substrate } incubated	2·4	83
3	Buffer + BeCl$_2$ } filtered ↓ filtrate + enzyme + substrate } incubated	14 0	1
4	Buffer + BeCl$_2$ } shaken with filter paper and decanted ↓ decantate + enzyme + substrate } incubated	2·8	80
5	Buffer + BeCl$_2$ + substrate } filtered filtrate + enzyme } incubated	13·9	2
6	Buffer + BeCl$_2$ + substrate } filtered ↓ filtrate + substrate } incubated	2·3	84

paper, as shown in experiment 4. Obviously the inhibition must be ascribed to the beryllium hydroxide precipitate. Experiments 5 and 6 differentiate between the following two possibilities: (*a*) influence on the substrate, for example, by adsorption in inaccessible form; (*b*) influence on the enzyme. This leads to the conclusion that the inhibition of alkaline phosphatase *in vitro* is caused by interaction between precipitated beryllium hydroxide and the enzyme, perhaps by co-precipitation. Under the experimental conditions described, the precipitate is not visible in the reaction mixture or on the filter paper. It can be made visible by addition of an alizarin dye, for example, alizarin bordeaux. After filtration a small amount of a coloured precipitate is visible on the paper.

In our opinion, the inhibition *in vitro*, as described above, bears no relation to the action of beryllium *in vivo*, notwithstanding the suggestion to the contrary by the development of rickets-like bone lesions on administration of beryllium salts to rats. Klemperer[3] ascribes the activation of succinic oxidase by beryllium to an alteration of the colloidal structure of the enzyme caused by the gelatinous precipitate of beryllium hydroxide. He states that this activation appears to be unspecific and of little toxicological significance. On the same grounds, in our opinion, the *in vitro* inhibition of alkaline phosphatase appears to be unrelated to beryllium rickets and other manifestations caused by beryllium *in vivo*.

Delayed Implantation in the Elephant Seal

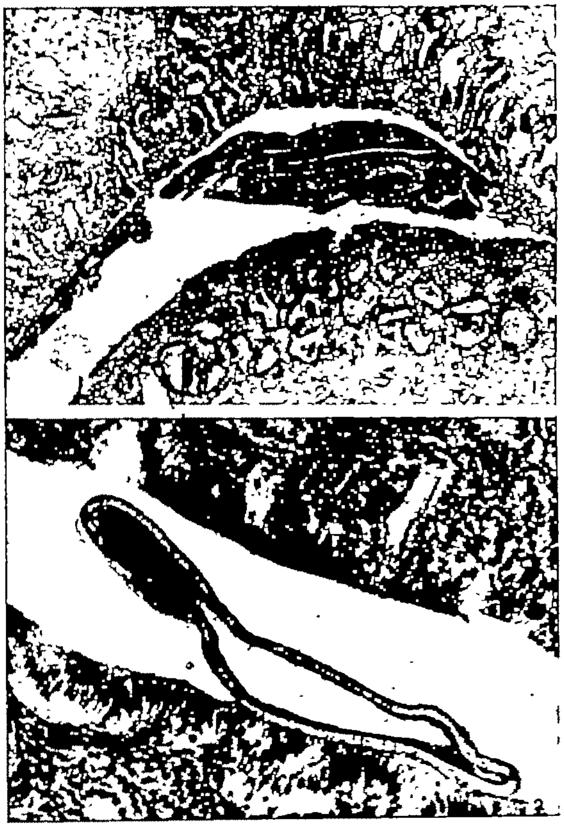
Since 1950, efforts have been made by biologists of the Australian National Antarctic Research Expedition at Heard Island to collect material for the study of the embryology of the elephant seal, *Macrorhinus proboscideus* (Peron and Lesueur). The task was rendered difficult by the fact that the female spends most of the year feeding at sea and only returns to land for parturition and moulting.

Copulation occurs during the last half of October and the first half of November, so that when harem cows come ashore to moult (between late December and late February), they must be from one to four months pregnant. It was thought that, by killing cows during the moulting season, a series of early fœtuses would be obtained.

Females were therefore killed throughout December 1952 and January and early February 1953; but although in almost every case a well-developed corpus luteum was found in one ovary, no sign of an embryo or of an area of implantation could be discovered in the uterus.

However, in late February and the first days of March 1953 five females were killed and in each case the lumen of the uterus was enlarged at one point to form a sort of pouch filled with a watery fluid. The mucosa in these areas appeared highly vascular; but microscopic examination failed to discover a fœtus.

The uteri were brought back to Australia and one 'pouch' sectioned. A 1·5-mm. embryo was found lying between folds of the uterine mucosa (Fig. 1). Very little chorionic tissue has so far been found, and in the sections so far examined only remnants



of fœtal membranes were located, indicating that the embryo may have been torn from its original implantation site when the uterus was first opened. The embryo was at the equivalent stage of development of a human embryo of about three weeks. Forebrain, nerve cord and ten somites are readily identifiable.

It was thought probable on the above evidence that in the elephant seal there is a delayed implantation such as occurs in the European badger, the American marten, the armadillo, the northern fur seal and other species. In such animals the egg develops to the blastocyst stage and then lies dormant, sometimes for months, before becoming implanted and continuing to develop.

Confirmatory evidence was discovered when the uterus of a seal killed in mid-December was sectioned and a 0·3-mm. blastocyst was found (Fig. 2). The blastocyst was enclosed in what appeared to be the much-thickened egg membrane, which was closely applied and probably attached to the uterine mucosa. No sign of implantation was observed.

Further sectioning of elephant seal uteri taken at different times in the moulting season is now being carried out in the hope of discovering more about the early embryology. A detailed account of these findings together with other information on the sexual cycle of the elephant seal will be included in a paper now in preparation.

Varietal Reaction of Jowar to Grain Smut

Jowar (*Sorghum vulgare*, L.), an important grain crop, occupies about 23 lakh acres in Uttar Pradesh, and the State stands third in its production in India. The crop is invariably attacked by a severe smut disease caused by *Sphacelotheca sorghi* (Link) Clinton. It causes usually 2–5 per cent infection in the crop; but as high as 65 per cent infection has been recorded in some fields. On the basis of 2 per cent loss, the grain smut is responsible for a loss of more than five thousand tons of grain or 15·5 lakhs of rupees in terms of money annually. Considerable work has been done in Bombay and Uttar Pradesh as well as in other States of India on the control of the smut by fungicidal seed treatments; but there seems to be no report available on the resistant varieties of jowar to grain smut in India. The work on testing some varieties of jowar against grain smut was therefore started in 1950 and continued up to 1952.

Twenty-seven promising varieties or cultures of jowar were tested for their resistance towards grain smut. The seeds of the varieties or cultures were first moistened with water and then thoroughly mixed with smut spores (mixed collection from all over the United Provinces) in the proportion of 1 : 100 and were sown on three different dates at fortnightly intervals to give varying conditions of environment. The percentage of smut was calculated by counting healthy and smutted heads in each variety or culture. They can be grouped as follows, according to average smut infection shown by them.

Resistant (Below 1 per cent infection)	*31B*, 4101
Moderately resistant (Below 5 per cent infection)	4403, *4404A*, *S.A.*7005, 4801(*a*), *4403B*
Susceptible (Below 15 per cent infection)	*30D*, 4108, *10N.K.*, *4404B*, *S.A.*5155–5, 4801, 48/2, 4801(*b*), *4404B-A*, 51/3
Very susceptible (Above 15 per cent infection)	*5T*, *8B*, *30C*, 18, *4106B*, 4109, *9N.K.*, 48/11, 48/10(*b*), 51/4.

Most of the very susceptible varieties showed 30–65 per cent infection.

It is evident from the results that the most popular varieties of jowar in the State, namely, *8B* and *5T*, are highly susceptible. The two cultures *31B* and 4101 proved to be highly resistant. Five cultures proved moderately susceptible. This information may prove useful in evolving varieties of jowar by combining desirable grain characters with resistance to grain smut.

We are grateful to Dr. T. R. Mehta, economic botanist (oilseeds, millets and pulses) to the Government, United Provinces, Kanpur, for the supply of jowar varieties and cultures employed during the investigation.

Chromosomes of *Phylloglossum drummondii*, Kunze

Phylloglossum, the monotypic genus of the Lycopodiaceæ, is confined to Australia and New Zealand, being represented by the single species, *Phylloglossum drummondii*. Much attention has been given to the morphology and anatomy of the plant over the past fifty years by Bower, Thomas, Osborn and other workers, and there has been much speculation on the evolutionary interpretation of its structure. A comprehensive review of all this work has been given, recently, by Hackney[1]; but at no time has the cytology of the plant been discussed.

Manton[2] deals in detail with the cytology of the lycopods of Europe only, and so does not include a study of the chromosomes of *Phylloglossum*.

It seems fitting, then, to record the chromosome number and arrangement in *Phylloglossum drummondii* observed in material collected at Heathmont, Victoria, in 1952. The stroboli were fixed in acetic-alcohol and preparations made by using the iron-aceto-carmine squash technique.

Fig. 1 shows a metaphase plate of the first meiotic division in polar view with 246 bivalents and 10 univalents, giving a diploid number of 502. Fig. 2 is a camera lucida drawing of Fig. 1. With such a large number it is difficult to obtain the necessary 'spread' of the chromosomes to be certain of the count; but, allowing for a good margin of error in observation, the haploid number is not less than 250 and not more than 255. The presence of univalents (marked *a* in Fig. 2 was verified by observations of unpaired chromosomes at the pachytene stage of meiosis.

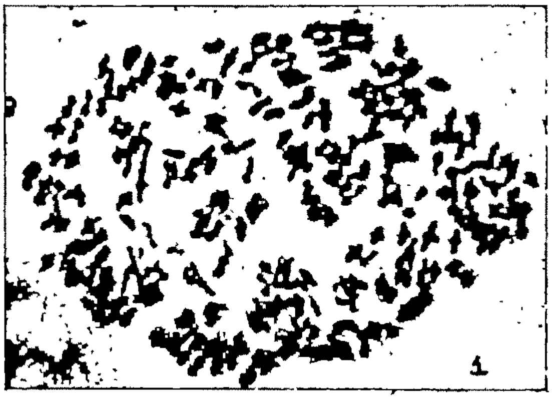

Fig. 1. Metaphase I; permanent aceto-carmine. (× 1,350)

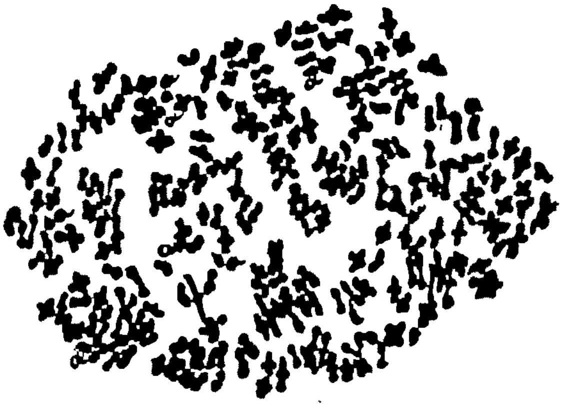

Fig. 2. Camera lucida drawing of Fig. 1, with univalents marked x. (× c. 1,500)

Manton, in discussing the chromosome number of *Lycopodium selago*, which has 113 bivalents and 37 univalents, suggests that the actual number is not as significant as the presence of univalents. These are an indication of irregular pairing and point to a possible hybrid origin. What the hybrid origin of *Phylloglossum* could be, with its restricted distribution and absence of related types, is a matter for speculation. In the possession of univalents *Phylloglossum drummondii* resembles *Lycopodium selago* more than the other lycopods studied by Manton.

Considering the number of chromosomes, however, *Phylloglossum drummondii*, with $2n = c.\ 502$–510, is similar to the primitive fern *Ophioglossum vulgatum*, with a diploid number of c. 500–520. Both would appear to have a chromosome number higher than any yet found in a wild plant-species.

It is hoped to complete a study of meiosis in *Phylloglossum drummondii* when more fresh material becomes available.

My thanks are due to Dr. E. I. McLennan for material and Dr. I. C. Cookson for help with photography.

Chromosome Numbers in the Desmids

The following chromosome counts have been made on culture material of the Desmidiaceæ:

	Closterium Leibleinii Kutz.	$n = 66$
612/1	*Cosmarium botrytis* Menegh.	$n = 26$
	C. botrytis	$n = 18$
612/5	*C. botrytis* (*forma* ?)	$n = c.\ 94$
612/10	*C. cucumis* (Corda.) Ralfs.	$n = 44$ and $n = 52$
612/3	*C. margaritiferum* (Turp.) Menegh.	$n = c.\ 64$
612/8a	*C. subtumidum* Nordst.	$n = 24$
637/1	*Hyalotheca dissiliens* (Sm.) Breb.	$n = c.\ 112$
652/1	*Netrium digitus* (Ehrenb.) Itzigs. and Rothe.	$n = 592$
664/2	*Pleurotaenium trabecula* (Ehrenb.) Naeg.	$n = 104$

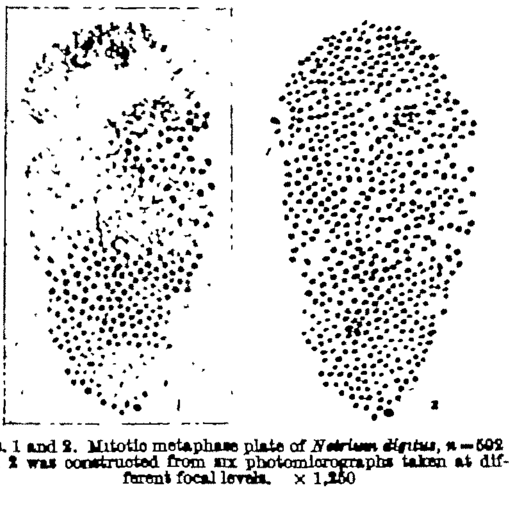
The majority of these cultures were obtained from the Cambridge Culture Collection of Algæ and Protozoa. The numbers preceding cultures from this source are those designated in that collection.

The count of $n = 18$ for *Cosmarium botrytis* has been previously published by me[1], but is included here for comparison. Similarly for *Pleurotaenium trabecula*, which I previously published under the erroneous name of *P. ehrenbergii*.

No morphological differences can be found between the $n = 18$ and the $n = 26$ clones of *C. botrytis*, nor between the $n = 44$ and $n = 52$ groups within the single clone of *C. cucumis*. The variation in the chromosome number in these species does not, therefore, appear to be due to polyploidy, but rather to the processes of fragmentation and/or fusion of chromosomes. For the former process to result in a transmissible increase in the number of chromosomes, a polycentric or 'diffuse centromere' type of chromosome organization must be present. Such an organization would be a concomitant of the process of fusion. Cytological confirmation that one or other of these types of chromosome organization exists in these two organisms has been obtained (that for *C. botrytis* having been previously published).

Comparison between the present counts and those of previous authors indicates that variation in the number of chromosomes in a species may not be confined to the genus *Cosmarium*. Previous counts which have been recorded are, for *Hyalotheca dissiliens*, $n = c.\ 12$ (Acton[2]), and for the forma *minor*, $n = 15$ (Pothoff[3]) and for *Netrium digitus*, $n = 32$ (Maguitt[4]) and $n = c.\ 30$ (Kopetzky-Rechtperg[5]). If such variation does occur, then these organisms also most probably possess the polycentric or 'diffuse centromere' type of chromosome organization.

Netrium digitus, with its chromosome complement of $n = 592$, has the highest chromosome number yet



Figs. 1 and 2. Mitotic metaphase plate of *Netrium digitus*, $n = 592$. Fig. 2 was constructed from six photomicrographs taken at different focal levels. × 1,250 recorded in the plant kingdom, the previous highest being that recorded by Manton[3] for *Ophioglossum vulgatum* (n = 250–260).

Relation between Dye Uptake and Cytoplasmic Streaming in *Amœba proteus*

GOLDACRE[1] has recently proposed a theory of osmotic work which is based, in part, on the manner in which streaming amœbæ accumulate vital dyes. Goldacre reported that streaming *Amœba discoides*, when placed in dilute solutions of neutral red, methylene blue, or brilliant green, accumulated the dye in the tail. Non-streaming amœbæ became stained only at the periphery. The experiments were repeated in this laboratory using *Amœba proteus*. The observations in general confirmed those reported by Goldacre, and further experiments employing hydrostatic pressure lend support to his interpretation.

Neutral red (0·005 per cent solution) and methylene blue (0·010 per cent solution) appeared first in the tail of streaming *A. proteus*; but in each case the dye was soon distributed throughout the cytoplasm in small vacuoles which eventually became coloured intensely red or blue. After 48 hr. in neutral red solution, the cytoplasm had a general pink tinge colour in addition to the intense accumulation of dye in the small vacuoles. The nucleus remained unstained. The amœbæ seen with the naked eye stand out as bright red spots. In a 0·002 per cent solution of brilliant green, amœbæ immediately ceased streaming and within a few hours underwent cytolysis.

The effect could be emphasized even more if amœbæ were kept at 12° C. for some hours. At such a low temperature most of the amœbæ became monopodal in form and streamed very weakly. Brought to room temperature (22° C.) in 0·005 per cent neutral red solution over a period of 3–4 min., the amœbæ began streaming more rapidly than controls and with a very marked accumulation of dye in the tail. The dye was soon distributed throughout the amœbæ by the moving plasmasol. Once the dye has been distributed, the colour contrast is insufficient to allow detection of any slightly higher concentration of dye in the tail.

If the dye uptake is causally related to streaming, amœbæ subjected to hydrostatic pressure sufficient to prevent streaming should also fail to accumulate dye. Amœbæ were placed in a 0·005 per cent neutral red solution and kept under a pressure of 425 atmospheres for 30 min. With this treatment the amœbæ rounded up, and the surface membrane could be distinguished as a blurred red line (in optical cross-section). No dye was detectable in the cytoplasm. The amœbæ thus treated did not resume streaming until 30–60 min. after release of the pressure. A second group of amœbæ was placed in 0·005 per cent neutral red solution and subjected to a pressure of 350 atmospheres for 30 min. Again the amœbæ rounded up, with a visible accumulation of dye on the surface; but within 60 sec. after release of the pressure they began streaming even more vigorously than the controls. When the amœbæ had moved a distance equal to but a fraction of their lengths, the surface membrane was no longer visibly 'stained', and dye was now clearly visible in the tail. With continued streaming the dye could be seen to be carried forward and distributed throughout the cytoplasm by the plasmasol.

The pressure experiment is of particular interest because it not only relates the dye uptake to visible streaming but also to unfolding of protein molecules, according to Eyring, Johnson and Gensler's interpretation of pressure effects on proteins[2].

In neutral red staining it was noticed that the tail of the amœba was slightly acid relative to the rest of the cytoplasm.

Finally, it should be emphasized that the observation of the accumulation of dye at the tail requires considerable time and patience; the effect will not be detected by the casual observer.

I wish to thank Dr. Daniel Mazia for his direction of this work.

D. M. PRESCOTT

Department of Zoology,
University of California,
Berkeley, California.
March 28.

---

[1] Goldacre, R. J., *Int. Rev. Cyt.*, 1, 135 (1952). Goldacre, R. J., and Lorch, I. J., *Nature*, 166, 497 (1950).

[2] Eyring, H., Johnson, F., and Gensler, R., *J. Phys. Chem.*, 50, 453 (1946).

PRESCOTT'S confirmation and extension of the results of Lorch and myself suggest the following comments:

(1) While the accumulation of neutral red in the tail of the amœba must often have been overlooked by the casual observer, it can readily be made visible by sucking away most of the dye solution in the hanging drop with a fine pipette, which improves the contrast. Better still, if the streaming of the amœba is inhibited by too high a concentration of dye, it can be restored by replacing the dye solution with culture medium, when the dye which has been adsorbed by the cortical gel over the whole surface of the amœba is completely released into the tail when the amœba has moved a distance equal to its own length.

Prof. J. F. Danielli informs me that students at King's College, London, have now regularly seen this phenomenon in a class experiment using *A. proteus*, which we have found behaves similarly to *A. discoides* in this respect.

(2) The slight acidity in the tail of the amœba reported by Prescott has sometimes been suggested as the cause of the accumulation of the partly ionized dye. Mere passive diffusion of the un-ionized molecular species through the membrane, to ionize again inside according to its ionization constant and the pH, would result in a higher concentration of the dye ion in the more acid region at equilibrium. However, experiment suggests that this difference in colour of the indicator between the tail and the cortical gel is not necessarily due to a change in pH, but to a change in the protein error of the indicator when the protein molecules fold up. It was found that when serum albumin, in a solution strongly buffered at pH 7 and containing a trace of indicator, was heated

on a water-bath and cooled to its original temperature, the colour of the indicator was different from that of the unheated control[1]. The glass electrode showed no change in pH, yet the apparent pH shown by the indicator had changed by about one unit. Unfolding of the serum albumin molecule was sufficient to reverse the sign of the protein error with phenol red. If protein molecules fold up in the tail as postulated by Goldacre and Lorch, it would be surprising on chemical grounds if there was no change in protein error and in apparent pH as measured with indicators.

Moreover, accumulation of neutral red was found to occur in *A. proteus* from solutions at pH 4, 5, 6, 7 and 8 (0·02 per cent dye with $M/200$ acetate and phosphate buffers checked by glass electrode), which could not occur if it depended only on passive diffusion between regions of slightly different pH inside and outside the amœba.

(3) The difference in colour of the neutral red indicator between the front and back of the amœba is at least partly an optical artefact due to the difference in concentration of the dye. It is impossible to compare pH values unless the concentration of the indicator is the same. Neutral red solutions in buffer at pH 8 appeared red when the dye concentration was high, and yellow when the concentration was low; also, the same dense neutral red solution at pH 8 placed in a tapering centrifuge tube appeared yellow at the narrow end and red at the wide end. A familiar example of a similar effect occurs in blood, the red cells of which appear yellow when viewed as individuals under the microscope. This dichroism has been explained by Wright[2] in terms of the properties of the Beer–Lambert law. Any indicator in its useful pH range has an unsymmetrical absorption curve, due to the presence of the two molecular species, and under these conditions the ratio of the transmitted light at two different wave-lengths is not constant, but changes with the concentration and the thickness of the solution; for the transmitted light is not proportional to the dilution, but to the anti-logarithm of the dilution, as indicated by the Beer–Lambert law, $I/I_0 = \exp(-kdC)$. Thus a change in concentration or thickness can simulate a change in pH.

Effects (2) and (3) above, working together under varying conditions, may account for the conflicting reports on the variation in pH at different parts of the amœba (see also refs. in footnote 3).

"Statistical Significance in Psychical Research"

We think it is important that readers of *Nature* should not be led by Mr. Spencer Brown's article on "Statistical Significance in Psychical Research" (*Nature*, July 25, p. 154) to think that there is ground for doubting the validity of the experimental work of the past twenty years in establishing the reality of phenomena commonly referred to as extra-sensory perception.

Mr. Brown says that, in demonstrations of telepathy, adequate control series have not been used and that control series would give equally curious results. The obvious and adequate control is to check series of guesses against packs of cards for which they were not intended. In many of the major experiments extensive checks of this kind have been made and the results have conformed to chance expectation. This seems to confirm the validity of the expectations on which the ordinary calculus of significance tests is based.

The thought in the paragraphs claiming to show that success in psychokinesis experiments assumes a contradiction certainly shows a confusion; but the confusion is Mr. Brown's. He seems to think that the applicability of significance tests to these experiments depends on the assumption that the dice throws form a random series. However, the question at issue is not whether the dice throws are random, but whether or not there is correspondence between the dice throws and the target numbers which have been randomly chosen.

Mr. Brown's experimental results on matching selected columns of random numbers may prove to be of interest to psychical research. But whether this is so or not can only be judged when these results, published with full details, have been criticized, and (if possible) confirmed by other workers. We cannot accept his inference that these results invalidate the conclusions drawn from experiments in extra-sensory perception.

(1) The issue on which I chose to argue[1] was clearly stated in my first paragraph. Taking the psychical research data (that is, the residuum when fraud and incompetence are excluded), I tried to show that these now threw more doubt upon existing presuppositions in the theory of *probability* than in the theory of *communication*. Thus, though not doubting the validity of some of the experimental work by accepted standards, I was led to question the validity of one of the accepted standards.

(2) I do not say that control series in psychical research merely *would* give statistically significant results; I say, more strongly, that they frequently do[2].

What have been called control series in some experiments have been made up by subsequent re-arrangement of the original material, so that lists of guesses are matched against cards for which they were not intended[3]. The validity of a control made up of subsequent selections from the main data is itself questionable, but in any event this procedure has not always led to insignificant results[4]. Only the insignificant scores occurring with this procedure are cited as evidence for the validity of the probability calculations used; when significant scores occur, they are taken as evidence for more extra-sensory perception, etc.

(3) I did not suppose that 'success' in psychokinesis experiments assumed a contradiction; I am not at all sure what such a supposition would mean. I argued that the claim for psychokinesis could not

be substantiated by statistical significance[7] alone, since the test of significance would be vitiated by any uncontrollable occurrence of statistically significant deviations in randomized data. If my critics will re-read the passage (pp. 11–21) referred to in ref. 6[5] of my paper, they will see that the conclusions of the imaginary tea-cup experiment may not be drawn if we have to take into account a mysterious agency which might uncontrollably upset the random presentation of the cups of tea. If such an 'agency' could thus 'upset' a process of randomizing, then all our conclusions drawn through the statistical tests of significance would be equally affected, including the conclusions from the 'psychokinesis' experiments themselves. (How are the 'target numbers' for the die throws to be 'randomly chosen'? By more die throws?) To speak of an agency which can upset *any* process of randomization in an uncontrollable manner is logically equivalent to speaking of an inadequacy in the theoretical model for empirical randomness. The mysterious 'agency' which 'upsets' the randomizer, like the luminiferous ether of an earlier controversy, becomes, with the obsolescence of the calculus in which it occurs, a superfluous term.

(4) Finally, I did not in my paper make the inference that the results I obtained in matching columns of random sampling numbers invalidated the conclusions drawn from experiments in extra-sensory perception. On the contrary, it was from supposing that the conclusions drawn from experiments in extra-sensory perception were already invalid that I made the inference that similar data might be found elsewhere. In other words, the inference I drew was the converse of that which my critics have drawn for me.

Sulphates in African Inland Waters

The communication on this subject by R. S. A. Beauchamp[1] emphasizes the need for agricultural experiments designed to explore possible sulphur deficiency in African soils. Mention is made of Storey and Leach's work on sulphur deficiency in Nyasaland which causes the tea yellows disease[2]. The Tukuyu district of the Southern Highlands province of Tanganyika is similarly affected, and since 1945, when D. W. Duthie of the Amani Research Station diagnosed the disease, application of sulphate of ammonia to tea soils has been a routine operation and has effectively controlled the disease.

When this Institute was started in 1950, a series of survey manurial experiments was planned, units of which are now in operation at Tukuyu and Mufindi (Southern Highlands, Tanganyika) and Kericho (Kenya Colony). A further extension to tea areas in Uganda is projected. These trials are based on the presence and absence of nitrogen, phosphoric acid, potash and elementary sulphur factorially combined. Nitrogen is supplied as sulphate of ammonia, potash as chloride, and phosphate as concentrated superphosphate in order to minimize the effect of adulterating sulphate ions; sulphur is applied in doses equivalent to those in the sulphate of ammonia dressings.

The two years results so far available appear in the annual report of the Institute. None of the experiments shows a response to sulphur, although it is known from other investigations being carried out that oxidation to available forms occurs within a matter of two to three months[3].

The Tukuyu results are of special interest in that the nitrogen effect is very marked and is of the same order as that shown in fertilizer experiments on tea in Ceylon[4]. It thus appears that the applications of sulphate of ammonia carried out during the six years prior to the start of the experiments have been sufficient to control the tea yellows disease during the following two years of experimentation, and that no limiting factor inhibiting specific nitrogen response has been operative.

So far, visits to the other tea districts in East Africa have not disclosed the characteristic symptoms of tea yellows, although tea has been grown in some districts for more than twenty-five years.

Mr. R. S. A. Beauchamp states, ". . . the only sources of gypsum in East Africa are those contained in the Cretaceous deposits along the coast of Tanganyika Territory . . .".

Somaliland seems to have been overlooked, for it is geographically included in, however politically apart from, 'East Africa'.

In the eastern half of British Somaliland and extending into Italian Somalia is found what may be the greatest deposit of gypsum/anhydrite in the world. Of Middle Eocene age, it is roughly 1,000 ft. in thickness and extends over some 27,000 square miles in the Protectorate alone[1]. Mutual benefit would accrue if some of this 5,000 cubic miles of rock could be worked to supply the sulphate needs of other parts of Africa.

Regarding Mr. Beauchamp's remarks about the scarcity of African waters with a notable sulphate content, I have recently published[2] analyses of 145 water samples from wells and other sources in British Somaliland and surrounding areas, all but two including sulphate estimations. Naturally many show very high sulphates, not uncommonly between 2,000 and 3,000 parts per million. At the tiny village of Eik in the Somaliland Haud the well-water yielded me a figure of 4,440 p.p.m. of sulphate ions, with total dissolved solids of the order of 10,000 p.p.m. This must rank as one of the most saline waters that is anywhere regularly used for human drinking, and it is so scarce and precious that the wells are fitted with padlocked trap doors!

FORTHCOMING EVENTS

Tuesday, September 29—Saturday, October 3

Association pour l'Étude Taxonomique de la Flore d'Afrique Tropicale (in the Departments of Forestry and Botany, South Parks Road, Oxford).—Second Plenary Meeting.

Friday, October 2

British Psychological Society, Industrial Section (in Room 105, London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 1 p.m.—Mr H. Murrell: "The Relationship of Ergonomics to Industrial Psychology".

Saturday, October 3

Association of Clinical Biochemists (joint meeting with the Association of Clinical Pathologists, in the Meyerstein Hall, Westminster Hospital Medical School, Horseferry Road, London, S.W.1), at 2.15 p.m.—Symposium on "Iron Metabolism" and other papers.

Engineers' Study Group (at 20 Buckingham Street, Strand, London, W.C.2), at 2.45 p.m.—Annual General Meeting.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Analysts (2), Assistant Experimental Officer grade (with recognized qualifications in chemistry)—The Secretary, Research Station, Long Ashton, Bristol (September 30).

Assistant in Physical Chemistry in the Department of Chemistry, University College, Dundee—The Secretary, The University, St. Andrews (September 30).

Mechanical Engineer (with university degree in mechanical engineering) for investigational and design work in a Section responsible for all mechanical site services, boiler houses, water works, plant and services in buildings, and for erection of experimental equipment—The Establishment Officer, Atomic Energy Research Establishment, Harwell, Berks, quoting 1/66/7/90 (October 5).

Senior Scientific Officer (preferably with first- or second-class honours degree in mechanical engineering, or equivalent qualification, and with postgraduate research experience, and also research experience on the creep and fatigue resistance of metals at high temperatures) in the Mechanical Engineering Research Laboratory, National Physical Laboratory, Teddington—The Civil Service Commission, Scientific Branch, Trinidad House, Old Burlington Street, London, W.1, quoting S.53/53 (October 6).

Assistant Lecturer in Geography—The Registrar, The University, Manchester (October 15).

Veterinary Officers and Research Officers in the Ministry of Agriculture and Fisheries—The Secretary, Civil Service Commission, Burlington Gardens, London, W.1, quoting 244–245/53 (October 15).

Senior Lecturer in the Department of Botany at the University of Natal, Pietermaritzburg, South Africa—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1 (October 16).

Technical Officer (with recognized qualifications in fuel technology or chemical engineering, and practical experience, preferably in some branch of the fuel industry) in the Headquarters Carbonization Department in London for duties concerned with technical developments in carbonization and allied fields and problems concerned with the quality of coke and carbonized fuels—The National Coal Board, Establishments (Personnel), Hobart House, Grosvenor Place, London, S.W.1, quoting TT/685 (October 29).

Chair of Physical Chemistry—The Registrar, The University, Nottingham (October 31).

Forest Officer to undertake teaching in all branches of Colonial Forestry and some part of undergraduate courses in forest management, mensuration and practical forestry—The Professor of Forestry, Imperial Forestry Institute, The University, Oxford (November 15).

Radcliffe Travelling Fellow in Astronomy—The Secretary, Board of Visitors, University Observatory, Oxford (March 31, 1954).

Abstractor (preferably with degree in engineering or physics, and knowledge of one or more of the following languages: Spanish, Italian, Swedish or French)—The Secretary, The British Shipbuilding Research Association, 5 Chesterfield Gardens, Curzon Street, London, W.1.

Assistant Mechanical Engineer (with administrative and organizing experience) with the Sudan Gezira Board to take charge of a new project, and be prepared to work on experimental lines—The Sudan Agent in London, Sudan House, Cleveland Row, St. James's, London, S.W.1, quoting "Assistant Mechanical Engineer 2412".

Engineers and Physicists, Senior Scientific Officer and Scientific Officer grades (Ref. A.246/52A) (with first- or second-class honours degree in physics or engineering, or high professional attainments such as corporate membership of appropriate professional institution, with suitable experience and responsibility); Experimental Officer and Assistant Experimental Officer grades (Ref. A.247/52A) (with university degree in science, engineering or mathematics, or graduate membership of appropriate professional institution) in Royal Naval Scientific Service Experimental Establishments in the London, Portsmouth and Weymouth areas, and in Scotland—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting appropriate Ref. No.

Lecturer (preferably with interest in the field of protein chemistry) in Biochemistry at the University of Adelaide—The Secretary, Association of Universities of the British Commonwealth, 5 Gordon Square, London, W.C.1.

Lecturer (with A.M.I.Chem.E. and/or degree qualification, and preferably with industrial experience) in Chemical Engineering, and an Assistant (with A.I.M. and/or degree qualification) in Metallurgy—The Registrar, Loughborough College of Technology, Loughborough, Leicestershire.

Lecturer and an Assistant Lecturer in Mechanical Engineering—The Professor of Mechanical Engineering, Imperial College, London, S.W.7.

Mechanical and Electrical Engineers, (*a*) Main grade (with university degree or equivalent diploma in electrical and/or mechanical engineering, and at least a two year apprenticeship); (*b*) Assistant grade (Graduate or Corporate Membership of the Institutions of Mechanical or Electrical Engineers, with appreciable electrical engineering experience and at least three years apprenticeship) in the Air Ministry, Works Department, for design, operation and maintenance of ground mechanical and electrical works services on R.A.F. stations at home and overseas and Civil Aviation stations—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting D.290/52A.

Mechanical Engineer (corporate member of either the Institution of Electrical or Mechanical Engineers, or equivalent qualifications, and with experience in Public Water and Electricity Supply undertakings, preferably overseas) in the Public Works Department, Sudan Government—The Sudan Agent in London, Sudan House, Cleveland Row, St. James's, London, S.W.1, quoting "M/Engineer 1824".

Meteorologists (2) in the Gold Coast, (*a*) (with honours degree in physics or mathematics, and not less than seven years experience in the Meteorological Office or Meteorological Branch of the Royal Navy, with some service in the tropics, and fully conversant with I.C.A.O. procedures) to supervise Accra Forecasting Office and related work of outstations, etc.); (*b*) (with honours degree in physics or mathematics, and experience in climatology, training of meteorological staff and forecasting) for work primarily on climatological investigation and research, and to assist in proper scientific training of local staff—The Director of Recruitment, Colonial Office, Great Smith Street, London, S.W.1, quoting CDE. 57/13/02.

Scientific Officers (Ref. A.230/53A) (*a*) Electrical Engineers or Physicists (with first- or second-class honours degree or equivalent qualifications) for work on centimetric transmitting and receiving equipment; (*b*) Theoretical Physicists or Mathematicians (with first- or second-class honours degree or equivalent qualifications) for work on radio propagation, radio frequency measurements, aerials and radiation problems. Experimental Officers (Ref. A.231/53A) (with H.S.C. Science) for development of electronic equipment, radio frequency measurements, especially at centimetric wave-lengths, and other detailed technical investigations, in the Radio Division, Royal Aircraft Establishment, Farnborough, Hants—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting appropriate Ref. No.

Senior Chemical Engineer (with A.R.I.C. or A.M.I.Chem.E., or equivalent, and at least three years experience in an industrial research organization) in the Division of Atomic Energy (Production), Sellafield, Cumberland, to be responsible for a section concerned with development of new chemical processes including design and operation of pilot plants—The Ministry of Supply, Department of Atomic Energy (Production), Risley, Warrington, quoting 499.

Senior Scientific Officer or Scientific Officer (with first- or second-class honours degree in mathematics or astronomy, and an interest in celestial mechanics, spherical astronomy or numerical computation, and preferably with research experience in one of these subjects) in H.M. Nautical Almanac Office, Royal Greenwich Observatory, Herstmonceux, Sussex, for work in the fields of celestial mechanics and positional astronomy—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.252/53A.

Soil Chemist, Plant Breeders (2), Agronomist, Statistician, Civil Engineers (Soil Conservation Section) (3), and Agricultural Engineers (Engineering Division) (2), (with appropriate honours degree or equivalent qualification) in the Research Division, Ministry of Agriculture, Sudan—The Sudan Agent in London, Sudan House, Cleveland Row, St. James's, London, S.W.1.

PROFESSIONAL AND ACADEMIC RESPONSIBILITY AND FREEDOM

A PASSAGE in the address which Sir John Maud delivered last October to the Federation of British Industries Conference on the universities and industry, in which he discussed the use made by the Civil Service of the university graduate and the qualities of the graduate that have proved most valuable, deserves consideration in a wider context. First and second among the valuable qualities—though not in any way implying that the university graduate had any monopoly of them—Sir John put integrity and courage. The administrative officer in the Civil Service, he said, particularly needs the characteristic type of integrity which the graduate should possess—a passionate respect for the truth, a respect which would set limits even to what a Minister could say. Sir John suggested that, from his experience of Civil servants, a Minister who wanted to answer a Parliamentary question in a way that was not true would have to draft the answer himself, and this referred also to all papers which Ministers send to the Cabinet when they wish to propound their own policy. There is a limit, he said, even to what can be said in Parliamentary debates, and it is set by the refusal of a self-respecting administrative officer to put forward a brief which is not justified by the facts.

That refusal, of course, demands courage as well as integrity, and while Sir John went on to illustrate his point further in regard to gaining acceptance for new ideas, there are reasons for specially welcoming this reference to the importance of integrity and courage, not only in the public service but also in public life. The sudden dismissal of Dr. Allen V. Astin from his post as director of the U.S. National Bureau of Standards in circumstances which suggest that an attempt was being made to influence a technical judgment or report by political or other considerations has deeply perturbed many American scientists and technologists; he has, of course, recently been reinstated. Scientists as well as others in Great Britain are not happy at the way in which Prof. W. A. Lewis has left the board of the Colonial Development Corporation. If these misgivings are, in fact, quite unfounded, the persistent refusal of the Secretary of State for the Colonies to give any explanation as to why the appointment was not renewed is all the more mysterious. Mr. Oliver Lyttelton can scarcely be unaware that existence of a belief, whether well founded or not, that the appointment was terminated because Prof. Lewis gave unpalatable advice to the Colonial Office, is unlikely to encourage the recruitment to the Colonial service of scientific and technical experts of the standard of professional ability, integrity and impartiality that is most desirable.

Nor would it be difficult to multiply examples where plain and independent speaking by the expert on public issues is important. Quite irrespective of the political issues of nationalization and its merits or demerits, the technician and transport engineer have a right to protest against the disregard of technical considerations, such as the adverse effect on technical efficiency if decentralization of railway regions is carried too far. The smooth and efficient operation of great public services cannot be secured if two great political parties insist on profoundly disturbing their work and keeping policy and organization in uncertainty by making them the plaything of party politics. Those who are concerned with the technical operation of transport or the iron and steel industry have a clear right to point out the difficulty of operating effectively, and at the same time to insist that the national interest demands imperatively that the future of such industries shall be determined on the basis of reasonable accommodation and not left to the prejudice or intransigence of political parties. Again, while Prof. S. Zuckerman's committee is considering the possibility of contamination of food through the use of insecticidal sprays in crop protection, as regards the wider question of additions to foodstuffs and the chemical manipulation of foods, the Government's attitude, as revealed in the House of Lords debate on June 10, reveals a disturbing reluctance to consider the whole question in its relation to health and disease.

It is against this background of the need both for integrity and courage as well as sound technical or professional judgment in public life, in the public service and in industry, and for independent centres of impartial, responsible criticism of public policy—the independent centres of reflexion of which Sir Hector Hetherington spoke in his Essex Hall Lecture—the judgment and integrity of which command confidence and respect, that the questions of academic freedom and the rights and responsibilities of universities are most appropriately considered to-day. This point of view, however, was not reflected in the discussions on "Science and Freedom" at the European Congress for Cultural Freedom held at Hamburg last July (*Nature*, 172, 445; 1953), although there was some serious discussion of influences which could hamper the free development of science in the modern world, and the University Grants Committee was several times commended as a model agent for the discrete distribution of government subsidies, without usurping the scientist's or scholar's right of self-direction. The Chancellor of the Exchequer took a similar view of academic freedom when he addressed the recent Congress of Universities of the Commonwealth at Cambridge.

Mr. Butler expressed the view that, while there is little danger of direct Government interference or of parsimony, there is a danger that the development of the universities might be moulded gradually, not so much by the independent desires of the universities themselves, as by the call for the production of particular types of specialists. Academic autonomy is impaired in fact, if not in name, by the granting or withholding of funds for particular purposes by external authority, such as the Government. This is, of course, the root of the objection to the ear-marked grant, as has been explained very fully by the University Grants Committee. It also lies at the root of the objections of the American universities to Federal assistance, as Dr. H. W. Dodds, president of Princeton University, explained to the same Congress, and was earlier emphasized by him and L. M. Hacker and Prof. Lindsay Rogers in the memorandum they submitted to the Commission on Financing Higher Education.

Such misgivings point to one reason why such a device as the University Grants Committee is unsuitable for American conditions; but as already stated, this is too narrow an approach to-day to the consideration of this question of academic freedom. Nor is the issue appropriately discussed solely from the angle which is suggested by current discussion on political influence. In his Castner Memorial Lecture to the Society of Chemical Industry last April on the role of technology in American chemical industry, Mr. R. C. Swain, while admitting that a very few men and women have used this cloak of academic freedom to cover subversive activities, was emphatic that this confers on governments no right of interference in academic matters; it is a problem that should be the responsibility of trained academic administrators and not of politicians.

Mr. Swain fully endorsed the conclusion reached by the Association of American Universities in a statement[*] on the rights and responsibilities of universities and their faculties, adopted on March 24, 1953: "We assert that freedom of thought and speech is vital to the maintenance of the American system and is essential to the general welfare. Condemnation of Communism is not to be interpreted as readiness to curb social, political or economic investigation and research. To insist upon conformity to current beliefs and practices would do infinite harm to the principle of freedom, which is the greatest, the central American doctrine".

The interest of this statement for British universities, however, lies only partly in its formulation of academic freedom as essential to social and national welfare. It lies even more in the derivation of its argument for, and defence of, academic freedom from a consideration of the nature of a university and its role in national life. Only, in fact, when the function of a university in the society and world of to-day is clearly understood can the significance of academic freedom be rightly appreciated and sound proposals formulated to safeguard it either from abuse or infringement.

In this statement, the Association of American Universities points out that the modern university is a unique type of organization; like its medieval prototype, it is an association of individual scholars, united in loyalty to the ideal of learning, to the moral code, and to the country and its form of government, representing diversified fields of knowledge and expressing many points of view. Freedom of enterprise, moreover, is as essential to intellectual as to economic progress, and a university must therefore be hospitable to an infinite variety of skills and viewpoints, relying upon open competition among them as the surest safeguard of truth, just as Milton argued. The whole spirit of a university requires investigation,

[*] The Rights and Responsibilities of Universities and their Faculties: a Statement by the Association of American Universities, adopted Tuesday, March 24, 1953. Pp. 16. (Princeton, N.J.: Dept. of Public Relations, Princeton University, 1953.)

criticism, and presentation of ideas in an atmosphere of freedom and mutual confidence. To enjoin uniformity of outlook upon a university faculty would put a stop to learning at the source.

This, the statement points out, is the real meaning of academic freedom, and it rightly adds that it is essential not only that the governing board should guarantee a faculty this freedom, but also that the reasons for such a guarantee should be understood by the public. From quite a different approach we thus find the same insistence on public understanding as has been emphasized in recent discussions as a condition for the continued effective functioning of the University Grants Committee in Great Britain. Moreover, the importance of public understanding is further emphasized when we consider the position of the university in relation to disputed questions of scholarship or matters of public policy, where both technical or scientific as well as political issues may be involved.

In all such matters, the Association of American Universities points out, a university does not take an official position of its own lest it in any way discourage or hinder the pursuit of truth or the advancement of knowledge. To fulfil his function, the university student or scholar must continue to analyse, test, criticize, and re-assess existing institutions and beliefs, approving when the balance of evidence supports them and disapproving when the weight of evidence is on the other side. Nor can such investigations be limited to the physical world. The fact that moral, social and political progress has not kept pace with mastery of the physical sciences points to the need in these spheres for more inquiry, criticism and inventiveness, including the study, if necessary, of unpopular ideas. Further, the statement recognizes frankly that the scholar may be compelled to challenge popular disapproval or prejudice. In the field of his own competence, the scholar may have a duty to speak and to proclaim truth even when it is unpalatable.

The freedom, and with it the responsibility, to proclaim the truth is one of the most important functions of the university in the modern world.

THREE HUNDRED YEARS OF AMERICAN PSYCHOLOGY

History of American Psychology

By A. A. Roback. Pp. xiv+426+28 plates. (New York: Library Publishers, Inc.; London: George Allen and Unwin, Ltd., 1952.) 42s. net.

DR. ROBACK has given us a learned and lively account of American psychology since 1640. His aim is to do justice to the pre-experimental period, which had previously been studied in detail only by W. J. Fay, and to deal more fully with certain problems than is possible in general historical works.

He divides the period under review into three stages: 1640–1890, 1890–1910, and 1910–50. The first phase begins with Harvard's earliest curriculum, the achievement of Henry Dunster, a clergyman educated in England. English, Scottish and German scholarship seems to have dominated the American academic world in Colonial days, and its leading figures displayed a keen interest in problems of a psychological character. Many such topics (for example, "The fancy produces real consequences") formed the subjects of theses submitted by Harvard candidates for a bachelor's degree in physics. Psychology was then a sub-division of physics known as pneumatics (or pneumatology).

Dr. Roback's treatment of the second phase covers more familiar ground. Its novelty lies in its vivid character studies. These are often based on personal acquaintance and on hitherto unpublished correspondence. German influence was predominant, especially the voluminous writings of Wilhelm Wundt (that "formidable philosophical cobbler", as Gasset calls him), though McKeen Cattell absorbed Galton's statistical ideas into the United States; and Titchener believed that his studies at Leipzig had not altered the English character of his thinking.

In the second half of the book Dr. Roback devotes himself to the third phase and becomes much more controversial in his emphasis and assessments. His comparative lack of enthusiasm for Hull's behaviour theory may be deduced from the scanty space allotted to it. Nor is he decided whether Prof. E. C. Tolman's elaborate system, embodying as it does elements of all the schools, is more than a 'colourful crazy quilt'. He reserves some very sharp words both for factor analysis and for operationism, while neo-scholastic psychology escapes lightly. Finally, after presenting the luminaries of psychology, he adds an annotated inventory of the lesser lights, the personified footnotes to history.

One of Dr. Roback's difficulties is the fact that many of America's most distinguished psychologists have been refugees from Nazi Germany whose fame was established before they left Europe. It remains to be seen whether the work of men like Wertheimer, Lewin and Köhler will leave a lasting mark on American psychology or whether they will suffer the fate of William MacDougall. We learn from Dr. Roback that the Americans looked upon MacDougall not only as an outsider, but also as a foreigner who wished to impose his views on them. It would be a mistake to overlook the profound differences between American and European points of view. According to Prof. Allport of Harvard, the Americans have "motorized" psychology, and he adds that "only behaviourism in both its muscle-twitch and operational versions is primarily American". This gives us a clue to the divergence.

A few decades ago, Dr. Roback tells us, Europeans believed that no psychology was to be expected in the land of the dollar. Nowadays there may be a belief that no psychology is to be expected in countries short of dollars. Prof. Boring, for example, has spoken of "the psychologist's handicap of living in England". We may be forgiven for wondering, therefore, what sort of history of American psychology would be written by a European. In 1930 Pierre Janet remarked to Dr. Roback, "Les Américaines—ils ont des édifices magnifiques, des laboratoires impressives—mais de psychologie . . ."; and K. R. Lorenz recently stated (in "Physiological Mechanisms in Animal Behaviour"), "an American journal masquerades under the title of 'comparative psychology' though to the best of my knowledge no really comparative paper has ever been published in it".

Evidently some Europeans do not share the Americans' estimate of their own work.

The American Psychological Association now has ten thousand members as compared with a handful at the turn of the century. We must wait to see whether the achievements of this army are commensurate with its increase in size. John Cohen

SCIENTIFIC WORK ON BARLEY

The Barley Crop

By Dr. Herbert Hunter. (Agricultural and Horticultural Series.) Pp. ix+187+12 plates. (London: Crosby Lockwood and Son, Ltd., 1952.) 21*s*. net.

Barley is one of the most interesting of all farm crops. It has a wider tolerance of climatic conditions, and therefore a wider geographical distribution than any other cereal, and its grain has a greater range of uses depending on its composition and the form in which its constituents exist. It has long been fortunate in its students and historians. Six years ago E. S. Beavan's remarkable volume "Barley, Fifty Years of Observation and Experiment" was published posthumously, and now Dr. Hunter has prepared this connected account of his well-known and highly valued experiments with this crop. These were begun in Ireland, where he was for long responsible for the barley investigations conducted by the Department of Agriculture in association with Messrs. Arthur Guinness and Co., an account of which he published in 1926 in a book also called "The Barley Crop". Since then much new material has accumulated. The National Institute of Agricultural Botany at Cambridge has been continuously studying barley varieties since 1919, and the Institute of Brewing ran a long series of chemical and field studies from 1920 onwards. The Danish investigators also have been very active and have produced some remarkably good varieties. Dr. Hunter has rendered a valuable service in putting together this material and making an interesting book of it.

The book opens with a detailed account of the botanical classification of the genus *Hordeum* and a brief history of barley in Britain from prehistoric times to the present day. The records go back to the Neolithic period: barley grains somehow got into the clay in the making of pots; they were burnt during the firing but left an impress in the clay from which it is possible to effect some measure of identification. Even in those days—five thousand years ago—both naked and hulled types occurred, the former predominating more and more as time went on; but in the Iron Age, and still more in the Anglo-Saxon period, the hulled barley was the more common. Some actual grains have been found which show that the type was six-rowed *H. hexastichum* as shown on Greek and early Roman coins: two-rowed barley was not found in Britain until just before the Christian era. However it got here, it is now our chief type; the six-rowed sorts are mainly winter or spring varieties not very widely grown.

When agricultural surveys were first made in Britain a number of different varieties were recorded in different parts of the country; some of them still survive and have proved of great value to plant breeders. Dr. Hunter has been strikingly successful with Spratt, crossing it with Archer to produce Spratt–Archer, one of the most popular malting varieties, and with Archer Goldthorpe to produce Camton, a short stiff-strawed variety that will stand up to high manuring, and, while not popular with maltsters, is of great feeding value.

The Danish breeder, H. A. B. Vestergaard, has produced at Abed in Lolland some outstanding varieties, early ripening and resistant to lodging; some of them, notably Kenia and Maja, have proved very useful in Britain. As the combined result of suitable varieties, high manuring for the preceding sugar beet, and sound management, the Danish farmers obtain the highest yield of barley in the world—51·8 bushels per acre; Great Britain comes next with 39·2 bushels.

The effect of manuring, weather conditions, cultural conditions and other factors on yield and quality of the grain are discussed with special reference to the Irish experiments; it would have been interesting to have compared these with the long series of experiments made under the Institute of Brewing scheme, particularly to see if the relations with rainfall were paralleled in Ireland.

In conclusion, the author discusses the objects at which the plant breeder should aim, rightly emphasizing the need for resistance to lodging. Most experts will agree with Dr. Hunter that high yield and high quality can be combined, but very high yields may be less compatible with high quality.

The book can be strongly recommended to all who are interested in barley: it gives in clear concise form an admirable summary of present knowledge of this most interesting crop. E. John Russell

THEORY AND APPLICATIONS OF FLUID DYNAMICS

High-Speed Aerodynamics

By Prof. Harold W. Sibert. (Prentice-Hall Aeronautical Engineering Series.) Pp. xiii+283. (New York: Prentice-Hall, Inc., 1948.) n.p.

Supersonic Aerodynamics

A Theoretical Introduction. By Edward R. C. Miles. Pp. xi+255. (London: McGraw-Hill Publishing Co., Ltd., 1950.) 34*s*.

Aerodynamics of High Speed

Facsimiles of Nineteen Fundamental Studies as they were Originally Reported in the Scientific Journals. With a Bibliography compiled by Prof. George F. Carrier. Pp. xi+286. (New York: Dover Publications, Inc., 1951.) Paper, 1.75 dollars; cloth, 3.50 dollars.

High-Speed Aerodynamics

By W. F. Hilton. Pp. ix+598. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1952.) 60*s*. net.

Essentials of Fluid Dynamics

With Applications to Hydraulics, Aeronautics, Meteorology and other Subjects. By Prof. Ludwig Prandtl. Authorized translation. Pp. x+452. (London and Glasgow: Blackie and Son, Ltd., 1952.) 35*s*. net.

Prof. H. W. Sibert's book is intended for undergraduate students of aeronautical engineering. The mathematical development is strictly elementary in character and is set out in full detail. Almost all the examples are numerical in character, and, although such computations are by no means to be despised, it is a melancholy commentary on the standards achieved in American colleges that it has not been possible to include any problems giving developments of the theory. The book is an admirably clear account of the foundations of high-speed aerodynamics. However, the derivation of the formula for the speed of sound as given in Chapter 5 is perhaps an exception to this general statement, as it seems to imply that there is no distinction between the speed of the fluid and the speed of sound through the fluid.

The range of the book can be estimated from the fact that it gives a derivation of the Busemann parabolic formula, and not the von Kármán formula for wave drag on a projectile. The formulæ for the lift and drag on rectangular wings of finite aspect ratio are given without proof.

The book contains a large number of practical applications to such matters as altimeters, air-speed indicators, problems of control and stability at high Mach numbers, and the determination of wind drag on a wake survey.

Dr. Miles's text-book is strictly of an introductory character, and is intended primarily for university students of aeronautical engineering whose mathematical equipment goes very little beyond the usual course in the calculus. The book therefore contains very full mathematical details of such matters as the theory of characteristics, and even fuller details of the construction of the potential equation in cylindrical and spherical co-ordinates. Curiously enough, Busemann's name does not appear in the index, although the Busemann coefficients are obtained in the last chapter. The theory of shock waves is given in considerable detail, together with a full account of the Taylor–Maccoll investigation of the supersonic flow over a right circular cone. The book contains a number of examples, a great many of which are numerical in character. The von Kármán theory of wave drag on slender pointed bodies of revolution is not given. Full particulars of the numerical theories problem are included. There is a detailed account of the graphical-computational method of characteristics for axially symmetric supersonic flow.

Mathematicians and physicists in English-speaking countries already owe a heavy debt of gratitude to Dover Publications of New York for making available so many classical treatises in different branches of mathematics and mathematical physics. Prof. Carrier's book contains a number of especially attractive features. It is addressed to students of theoretical aerodynamics, and consists of photographic facsimiles of nineteen original studies, including the famous papers by Rankine and Taylor on shock waves, of Glauert on the effect of compressibility on lift, the pioneer investigations of Prandtl, Busemann and von Kármán, together with papers by Possio, Lighthill, Tomotika and Tamada, and many others. It is therefore an invaluable resource book for students in this subject.

There can be no doubt that the initiative of the Dover Publications in producing a super students' edition will be greatly appreciated. The present volume is also enriched with a very useful bibliography.

Hilton's book is a lively and exciting account of high-speed aerodynamics written especially for the aeronautical engineer. The author is certainly to be congratulated on the success with which his literary style conveys to the reader the sense of interest and importance and urgency of the problems which he discusses. The book covers almost the entire field of high-speed aeronautics. It begins with a general survey of the basic observational and experimental effects about subsonic, transonic and supersonic flow. This section very rightly opens at once with a discussion of shock stall and its effects upon drag. Then follow the consideration of compressibility, effects on lift and pressure, a study of the effect of shock stall on pitching moment, and a valuable chapter on stability and control. This, however, could have been improved if the definition of the coefficient a_1, a_2, b_1, b_2 were given at the very beginning instead of being indicated in casual asides.

The next section gives a good summary of the theory of supersonic flow over wings of infinite aspect ratio, of finite aspect ratio, and over pointed bodies of revolution. The theory of conical flow is referred to very briefly, so briefly indeed that it is unlikely that the terse summary on pp. 312–313, for example, would convey very much to the practical designer. In this connexion, it is a pity that Evvard's elegant theory of tip effects has not been included.

The third section gives a very interesting account of the high-speed wind tunnels, and of the special apparatus and techniques which are needed for high-speed measurements.

The fourth and concluding section of the book contains the formal mathematical theory of shock waves, together with some valuable sections on propellers and jet propulsion.

The author writes throughout as a practical tunnel man who has gained his experience at the National Physical Laboratory, Teddington, and the Applied Physics Laboratory, Washington. His eyes are always firmly fixed upon the practical problems and upon the limitations of the approximate theories which have been devised to correlate experimental observations. There are numerous original features in the book, such as the use of "carpet diagrams" for the representation of the variation of lift coefficients with incidence and Mach number. The author does not hesitate to express his personal opinions in very decisive language, and there are places in which some of the details of his presentation may be questioned as not entirely accurate; but the broad general picture is certainly painted with energy and enthusiasm, and there is no doubt that this book will form a most valuable addition to the library of every student of high-speed aeronautics.

"The Essentials of Fluid Dynamics", by Prandtl, is a magnificent account of the physical basis of fluid dynamics by one who did so much to create the subject by his own researches. The emphasis in this work is essentially upon the experimental data, and upon the engineering applications, but the mathematical theory, although maintained on a strictly elementary level, is sufficiently developed to correlate physics and engineering. The present work will naturally suggest a comparison with the book by Tietjens on "Fundamentals of Hydro and Aero Dynamics", which was based on Prandtl's lectures, and translated into English by Prof. Rosenhead in 1934. The present book by Prandtl himself covers far more ground, and as regards mathematical theory is, in the reviewer's opinion, considerably simpler than the earlier work. Prandtl covers a vast field, including hydrostatics, hydraulics, aeronautics, meteorology, theory of turbulence, and lubrication. The aerodynamical applications are, of course, of the greatest importance, and they include a good elementary account of the theory of aerofoils, propellers and windmills, together with a good introduction to supersonic flow. The section on hydraulics includes an introduction to the theory of open water courses, and shock waves on running water, together with a sketch of the theory of water turbines and pumps. The extensive section on meteorology gives an account of the basic theory of winds and of the general circulation of the air over the surface of the earth. Numerous other topics are covered in this book, including, for example, the theory of heat transfer and lubrication; but perhaps enough has been said to indicate its immense range.

Throughout this great survey, the hand of the master is evident in the powerful use of quite elementary theory to correlate complex phenomena in applied dynamics. On one hand, the book is admirably suited to a student who is approaching the subject for the first time and who wishes to start from its physical basis; on the other, it is, in fact, almost a small encyclopædia which can be used with great profit as a book of reference by the most advanced research students.

RADIO TECHNIQUES FOR RADAR

Radio and Radar Technique

By Dr. A. T. Starr. Pp. xviii+812. (London: Sir Isaac Pitman and Sons, Ltd., 1953.) 75s. net.

THE great advances in radio and electronic techniques which have taken place in the past two decades were largely stimulated by the war-time work on radar. Most of this work has already been published in a vast number of papers in the technical and scientific journals. The American and some British work has been collected together in the very comprehensive series of books prepared by the Radiation Laboratory, Massachusetts Institute of Technology, and published by McGraw-Hill. A good deal of the British work has also appeared in the much more compact but still fairly comprehensive series published by the Cambridge University Press. The aim of the present book is to compress most of this work into a single volume. The author has of necessity had to exercise discrimination in choice of material, leaving aside much that is only of limited interest or has become obsolete. That he has succeeded in covering the field in a single volume, even though somewhat bulky, is no small achievement, and there will be many who will prefer to have the material for easy reference in this form. Most of the subject-matter has already appeared in print; but the author frequently adds valuable hints for the engineer based on his own wide experience of these techniques. The compression necessary in such a volume will, however, lead most serious workers in the field to read the more specialized books on the different aspects of the subject which have already been published.

The main broad advances which have been made lie in the use of circuit techniques to generate the wide variety of wave-forms which enable modern electronic equipment to carry out such complex functions, and in the extension of the usable radio spectrum to the microwaves. Since much of the equipment was designed to work at the limits set by random fluctuations of a fundamental nature, a much better appreciation of the properties and character of electrical 'noise' was obtained. These matters are dealt with, and, in particular, the development of valves for the generation of microwaves is discussed. Chapters are also included on aerials and waveguides, and on the principles of modulation and communication of information generally.

Some mathematical treatment is given in the text; but the bulk of the theory is relegated to a long series of appendixes which occupy about one-quarter of the book. A bibliography is given at the end of each chapter; but this seems to have been chosen rather arbitrarily, and is by no means a complete account of the original papers nor a suitable guide for a beginner to the literature on the subject. Frequently reference is made to war-time reports of Government establishments. These reports are not generally available, and in any event contain material which has been published elsewhere. The book is well produced though the scale of many of the figures is too small for numerical use. For a book containing such a wealth of information the price is not excessive.

R. A. SMITH

MASS SPECTROMETRY

Mass Spectrometry

Report of a Conference organized by the Mass Spectrometry Panel of the Institute of Petroleum and held in Manchester, April 20–21, 1950. Pp. vi+205. (London: Institute of Petroleum, 1952.) 30s.

MASS spectrometry has rapidly become a technique of major importance in both routine testing and research investigations, and it was with the object of assisting in the application of this technique that the Mass Spectrometry Panel of the Institute of Petroleum was formed. The present volume reports the proceedings of a conference, organized by the panel, held in Manchester in 1950, and is a valuable addition to the literature on this subject.

Fourteen papers by established workers, surveying almost the whole field of mass spectrometry, are conveniently divided into four distinct groups, the first group dealing, appropriately, with the fundamental problem of the ionization and dissociation of molecules, and comprising four papers covering topics such as the measurement of appearance potentials and the consideration of the information derived from these, the determination of bond dissociation energies, and the detection of free radicals. The second group is concerned with instrumental aspects of mass spectrometry and contains a description of a French mass spectrometer followed by a paper discussing aspects of ion source design—one of the most important features of the modern mass spectrometer.

Applications of the mass spectrometer and the preparation of standard gases for calibration purposes are dealt with in the third and fourth groups; these are of more general interest and may, therefore, be the sections of greatest appeal to the reader not closely connected with this type of work, since the subjects discussed include isotope enrichment, isotope abundance measurements, syntheses using carbon-13, and some uses of stable isotopes. Also included in this section is a valuable discussion of the problems involved in the preparation of standard hydrocarbon samples.

A most acceptable feature is the provision of a very complete and classified bibliography on mass spectrometry from 1938 to the end of 1950; this in no small measure makes amends for the delay in the publication of the report.

JAMES BELL

'ACTIVELY ACQUIRED TOLERANCE' OF FOREIGN CELLS

By Dr. R. E. BILLINGHAM*, L. BRENT and Prof. P. B. MEDAWAR, F.R.S.

Department of Zoology, University College, University of London

THE experiments to be described in this article provide a solution—at present only a 'laboratory' solution—of the problem of how to make tissue homografts immunologically acceptable to hosts which would normally react against them. The principle underlying the experiments may be expressed in the following terms: that mammals and birds never develop, or develop to only a limited degree, the power to react immunologically against foreign homologous tissue cells to which they have been exposed sufficiently early in fœtal life. If, for example, a fœtal mouse of one inbred strain (say, *CBA*) is inoculated *in utero* with a suspension of living cells from an adult mouse of another strain (say, *A*), then, when it grows up, the *CBA* mouse will be found to be partly or completely tolerant of skin grafts transplanted from any mouse belonging to the strain of the original donor.

This phenomenon is the exact inverse of 'actively acquired immunity', and we therefore propose to describe it as 'actively acquired tolerance'. The distinction between the two phenomena may be made evident in the following way. If a normal adult *CBA* mouse is inoculated with living cells or grafted with skin from an *A*-line donor, the grafted tissue is destroyed within twelve days (see below). The effect of this first presentation of foreign tissue in adult life is to confer 'immunity', that is, to increase the host's resistance to grafts which may be transplanted on some later occasion from the same donor or from some other member of the donor's strain. But if the first presentation of foreign cells takes place in fœtal life, it has just the opposite effect: resistance to a graft transplanted on some later occasion, so far from being heightened, is abolished or at least reduced. Over some period of its early life, therefore, the pattern of the host's response to foreign tissue cells is turned completely upside down. In mice, it will be seen, this inversion takes place in the neighbourhood of birth, for there is a certain 'null' period thereabouts when the inoculation of foreign tissue confers neither tolerance nor heightened resistance—when, in fact, a 'test graft' transplanted in adult life to ascertain the host's degree of immunity is found to survive for the same length of time as if the host had received no treatment at all.

Earlier Work

The literature of experimental embryology is rich in evidence that embryos are fully tolerant of grafts of foreign tissues. It is less well known (though no less firmly established) that embryonic cells transplanted into embryos of different genetic constitutions may survive into adult life, although their hosts would almost certainly have rejected them if transplantation had been delayed until after birth. The transplantation of embryonic melanoblasts[1] provides the most conspicuous evidence of this phenomenon—not because melanoblasts are peculiar in their immunological properties, but simply because their genetic origins are at once betrayed by the pigmentation of the cells into which they ultimately develop. Unfortunately, experiments with embryonic melanoblasts, having been done with quite different purposes in mind, do not make it possible to decide whether survival into adult life is due to an antigenic adaptation of embryonic cells which have been obliged to complete their development in genetically foreign soil, or whether it is due to a suppression or 'paralysis'[2] of the host's immunological response.

An exactly comparable phenomenon has been described by Owen[3], who found that the majority of dizygotic cattle twins are born with, and long retain, red blood cells of dizygotic origin: each calf contains a proportion of red cells belonging genetically to itself, mixed with red cells belonging to the zygote lineage of its twin. There is no reason to doubt that this is because the cattle twins, being synchorial, exchange blood in fœtal life through the anastomoses of their placental vessels. (This is not a peculiarity of cattle, for a human twin with red cells of dizygotic origin has lately been described[4].) Inasmuch as the provenance of the red cells was revealed by their reactions with specific agglutinins, it is most unlikely that the survival of foreign erythrocyte-forming cells into adult life was made possible by any kind of antigenic adaptation. Moreover, we have found that the majority of cattle twins at birth and for long after are fully tolerant of grafts of each other's skin[5]. Being freshly transplanted, these grafts can have had no opportunity to 'adapt' themselves antigenically to foreign hosts, but they survived nevertheless.

The experiments of Cannon and Longmire[6] have a direct bearing on the phenomenon of actively acquired tolerance. About 5–10 per cent of skin grafts exchanged between pairs of newly hatched chicks of different breeds are tolerated and survive into adult life; but the percentage of successes falls rapidly as the age at which the chicks are operated increases, and reaches zero by the end of the second week. These results will be referred to later.

Experiments with Mice

A single experiment will be described in moderate detail: the recipients were mice of *CBA* strain, the donors of *A* strain. The data for transplantations between normal mice of these strains are as follows. The median survival time of *A*-line skin grafts transplanted to normal *CBA* adults (regardless of differences of sex, or of age within the interval 6 weeks–6 months) is 11·0 ± 0·3 days[7]. In reacting against such a graft, the host enters a state of heightened resistance; a second graft transplanted up to sixty days after the transplantation of the first survives for less than six days, and immunity is still strong, though it has weakened perceptibly, after four months. Heightened resistance may be passively transferred to a normal *CBA* adult by the intraperitoneal implantation of pieces of lymph node excised from a *CBA* adult which has been actively immunized against *A*-line skin[8].

In the experiment to be described (Exp. 73), a *CBA* female in the 15–16th day of pregnancy by a

---

* British Empire Cancer Campaign Research Fellow.

CBA male was anæsthetized with 'Nembutal', and its body wall exposed by a median ventral incision of the skin. The skin was mobilized but not reflected, and particular care was taken not to damage the mammary vessels. By manipulation of the abdomen with damped gauzes, six fœtuses were brought into view through the body wall. Each was injected intra-embryonically with 0·01 ml. of a suspension of adult tissue cells through a very fine hypodermic needle passing successively through the body wall, uterine wall, and fœtal membranes. (The inoculum itself, consisting of a suspension in Ringer's solution of small organized tissue clumps, isolated cells, and cell debris, had been prepared by the prolonged chopping with scissors of testis, kidney and splenic tissue from an adult male *A*-line mouse.) After injection of the fœtuses, the skin was closed with interrupted sutures.

Five healthy and normal-looking young were born four days later; of the sixth fœtus there was no trace. Eight weeks after their birth, when the lightest weighed 21 gm., each member of the litter was 'challenged' with a skin graft from an adult *A*-line donor. The first inspection of the grafts was carried out eleven days later, that is, at the median survival age of *A*-line skin grafts transplanted to normal *CBA* hosts. The grafts on two of the five mice were in an advanced stage of breakdown; the grafts on the other three (one male and two females) resembled autografts in every respect except their donor-specific albinism. Each of these three grafts became perfectly incorporated into its host's skin and grew a white hair pelt of normal density and stoutness. Fifty days later, one of the three mice received a second *A*-line graft from a new donor, and this graft also settled down without the least symptom of an immunological reaction.

The graft on one of the three animals underwent a long-drawn-out 'spontaneous' involution, beginning somewhat before the 75th day after transplantation and ending with complete breakdown shortly after the 91st day. The other two mice were made the subjects of an experiment[8] designed to show that acquired tolerance is due to a failure of the host's immunological response and not to an antigenic adaptation of the grafted cells. When the two grafts were of 77 and 101 days standing, respectively, and still in immaculate condition, their hosts were inoculated intraperitoneally with chopped fragments of lymph nodes from normal *CBA* mice which had been actively immunized against *A*-line skin. The grafts began to deteriorate 2–3 days later, with signs of vascular congestion and stasis; contracture, hardening and discoloration took place progressively, and the grafts were reduced to dry scabs by the fourteenth day after the nodes had been implanted. It follows that tolerant hosts are fully capable of giving effect to a state of immunity which has been elicited by proxy, and that the tolerated grafts have not lost their ability to respond to it.

The fertility of the mice was entirely unimpaired. Both females repeatedly bore litters of normal size by their male litter mate. When they had grown up, two litters (of six and eight respectively) were challenged with grafts of *A*-line skin. Breakdown of all the grafts was far advanced or complete by the eleventh day after their transplantation.

The results of Exp. 73 demonstrate the great (but not necessarily indefinite) prolongation of the life of homografts made possible by a pre-emptive exposure of their hosts to foreign homologous cells. Beyond this, they demonstrate (*a*) that this prolongation of life is not due to an antigenic transformation of the grafts, nor to a competitive absorption of antibodies by, for example, cells of the fœtal inoculum which had survived into adult life; and (*b*) that acquired tolerance is either not transferred to, or is too weak or too ephemeral to make itself evident in, the offspring.

Two of the five mice of Exp. 73 gave no evidence of increased tolerance of *A*-line cells. We suppose that this was because they were imperfectly injected. Only in one experiment so far has every injected fœtus given rise to a tolerant adult.

The more important results obtained from the investigation of other litters may be summarized as follows. (1) The conferment of tolerance is not of an all-or-nothing character; every degree is represented, down to that which gives the test-grafts only a few days of grace beyond the median survival time of their controls. (2) The conferment of tolerance is immunologically specific. Thus a *CBA* mouse made tolerant of *A*-line tissue, or vice versa, retains the ability to react with unmodified vigour against skin from a donor belonging to a third strain, *AU*. (Equally clear evidence of the specificity of acquired tolerance is given in the following section.) But it has so far been our experience that the transplantation of (say) *AU* skin to a *CBA* mouse that is tolerant of *A*-line cells will elicit a reaction which, in addition to destroying the *AU* graft, causes an *A*-line graft already in residence to go through a severe immunological crisis. Although we have evidence of a sharing of tissue antigens between strains *A* and *AU*, this phenomenon is difficult to interpret, for the antigens common to strains *A* and *AU* are merely a sub-group of those to which the *CBA* host is manifestly unresponsive. It may therefore turn out that the continued well-being of a tissue homograft upon a tolerant host depends upon the quiescence of the antibody-forming system, and that if this is awakened by tissue antigens other than those of which the host is tolerant, antibodies directed against its, until then, tolerated graft may be formed as well. (3) A wide histological variety of tissue cells is capable of conferring tolerance to homografts of skin. It is by no means obligatory that skin cells, or even epithelial cells, should be among them. (4) We have inoculated ninety-six new-born mice with adult or fœtal tissue cell suspensions to decide whether tolerance can be conferred by exposure to foreign cells at this relatively advanced stage of development. The majority received a single inoculation of cells as soon as possible after birth; a small subgroup of these was injected with 0·05 mgm. cortisone acetate on the same occasion and several more times during the first week of life in an attempt to delay the maturation of the antibody-forming system[9]. The remainder of the new-born mice received repeated injections of foreign tissue cells in increasing quantities over the period of a month from birth. In all, only nine mice (about 10 per cent: cf. the experiments of Cannon and Longmire referred to above) showed an increase of tolerance when tested with a skin graft from the donor strain, and six of these were members of a single litter of eight which had received a single inoculation of cells, without cortisone, immediately after birth. It is of particular interest that when challenged with skin grafts in adult life the great majority of inoculated new-born mice showed neither tolerance nor enhanced resistance. New-born mice are, in general, too old for a tissue inoculum to confer tolerance, and too young for it to confer immunity; the epoch of birth represents a null period during which the net outcome of exposure to foreign cells is to leave its subjects in a state of unaltered reactivity. (5) Grafts removed from hosts which have tolerated them, and then transplanted to normal mice of the host's strain, survive 2–3 days longer than freshly transplanted homografts of normal skin. Such homografts cannot, however, be compared directly with homografts of normal skin, because a high proportion of the corium of each will probably have been replaced by cells and cellular derivatives of host origin.

Preliminary Experiments with Chickens

Donors and recipients in these experiments were of Rhode Island Red and White Leghorn breeds, respectively. Skin transplanted from two weeks old Rhode Island Red chicks to White Leghorn recipients of the same age, using Cannon and Longmire's methods[8], is completely destroyed within ten days of grafting, to the accompaniment of an inflammatory reaction of conspicuous violence.

The embryonic chick is particularly well suited to experiments which make use of cellular inoculation, because the intravenous route is so easily accessible. Using methods demonstrated to us by Dr. C. Kaplan, whose help has been of the greatest value, we have obtained successful results by transfusing 0·2 ml. unmodified whole blood from an 11–12 day old embryonic Rhode Island Red donor into a chorio-allantoic vein of a White Leghorn embryo of the same age. Fourteen days after hatching, a test-graft of skin was transplanted to the recipient from its original donor. In seven such trials, five grafts showed prolongation of survival; of these, three succumbed within fifty days to the accompaniment of very much subdued inflammatory changes, and two still survive, with normal growth of red feathers, to the present time (125 days).

The success of these experiments has been found to depend on the strict pairing of donors with recipients. The transplantation of skin between our Rhode Island Red chicks when two weeks old showed them to be a highly heterogeneous assembly, in spite of their uniformity of breed characters. It is therefore understandable that chicks made tolerant to grafts from one Rhode Island Red donor will not, in general, accept grafts from another. This strict specificity of acquired tolerance has made it difficult to test the efficacy of grafts transplanted to the chorio-allantois, for an embryonic donor must be killed to provide tissues suitable for grafting. This difficulty has been circumvented by killing a young hatched donor, storing its skin[10] for later use in the test operation, and grafting fragments of a wide variety of its tissues upon the chorio-allantoic membrane of 10–11 day old White Leghorn recipients. Tolerance is conferred less regularly and less completely by this method than by blood transfusion: only three out of seven such experiments have yielded test grafts which survived for longer than twice their normal expectation of life, and those which have done so have given evidence of chronic low-grade inflammatory changes.

Washed blood corpuscles are as effective as whole blood in conferring tolerance; plasma is therefore a dispensable ingredient. If adult blood proves to be capable of conferring tolerance, it should be easy to decide whether red cells or white cells or both are efficacious.

Discussion

It is one of the predictions of Burnet and Fenner's[11] theory of immunity that the exposure of animals to antigens before the development of the faculty of immunological response should lead to tolerance rather than to heightened resistance. The homograft immunity system is particularly well suited to the appraisal of such a hypothesis, because the antigens are at once powerful, innocuous and persistent. For this reason, no great weight should be attached to failure of the experiments of Burnet, Stone and Edney[12] to verify it. It must be emphasized, however, that our experiments do not yet bear upon the fundamental problem of whether the production of antibodies represents an *inherited* derangement of protein synthesis, that is, a transformation which can persist through repeated cell divisions after the disappearance of the antigen originally responsible for it. It would be a highly significant fact if a transient exposure to antigen in fœtal life could confer a permanent or very long-lasting tolerance; but in our present experiments there is no reason to doubt that at least some of the cells of the fœtal inoculum survived as long as the tolerant state which they were responsible for creating. At all events, any complete theory of antibody formation must be competent to explain two sets of facts: that although embryos do not make antibodies, they respond to antigens in a manner that prejudices their ability to do so in later life; and that acquired tolerance is highly specific, for antibody-forming cells can be prevented from responding to one antigen without impairing their capacity to respond to any other.

A state of tolerance similar in principle to that which we have described may not necessarily depend upon an exposure to antigens in fœtal life. Phenomena which occur in adult life and which may be cognate with tolerance induced by fœtal inoculation include: (*a*) the highly specific 'immunological paralysis' of mice by the administration of relatively high doses of pneumococcal polysaccharide, made clear by the important experiments of Felton[9]; (*b*) that restraint of certain drug allergies in guinea pigs which, so Chase[13] has shown, may be brought about by the oral administration of the sensitizing chemical—an observation of particular interest, in view of the affinity between transplantation immunity and sensitization reactions of just this type[14]; and (*c*) the enhancement of the growth of tumour homografts by treatment of their prospective hosts with a variety of lyophilized tissue preparations, revealed by the work of Casey, Snell, Kaliss and their colleagues[15]. The relationship between these various phenomena has yet to be determined. We propose to investigate the hypothesis that exposure of the adult antibody-forming system to what may be called a 'tissue hapten' preparation—that is, to tissue ingredients which, although not themselves antigenic, contain the determinant groupings that confer specific activity upon complete antigens—may have the same kind of effect as that produced by an exposure of the immature antibody-forming system of the fœtus to complete antigens.

Actively acquired tolerance may not be a wholly artificial phenomenon. We are inquiring into the possibility that it may occur naturally by the accidental incorporation of maternal cells into a fœtus during normal development.

In dizygotic twin cattle of unlike sex, the confluence of fœtal vessels that leads to red cell chimaerism[3] and tolerance of homografts[4] has long been known to be associated with infertility of the female. In our present experiments, tolerance has been conferred upon female mice by inoculation with male cells without affecting their fertility. The two phenomena are therefore separable, although in cattle they go together and share an anatomical pre-requisite in common; but this is an inference that leaves entirely open the question of whether or not the freemartin state is due to a purely humoral influence of the male fœtus upon its synchorial female twin.

The experiments described in this article will in due course be reported on in full.

Summary

(1) Mice and chickens never develop, or develop to only a limited degree, the power to react immunologically against foreign homologous tissue cells with which they have been inoculated in fœtal life. Animals so treated are tolerant not only of the foreign cells of the original inoculum, but also of skin grafts freshly transplanted in adult life from the original donor or from a donor of the same antigenic constitution.

(2) Acquired tolerance is immunologically specific: mice and chickens made tolerant of homografts from one donor retain the power to react against grafts transplanted from donors of different antigenic constitutions.

(3) Acquired tolerance is due to a specific failure of the host's immunological response. The antigenic properties of a homograft are not altered by residence in a tolerant host, and the host itself retains the power to give effect to a passively acquired immunity directed against a homograft which has until then been tolerated by it.

(4) The fertility of tolerant mice is unimpaired.

TRANSMUTATION OF THE ELEMENTS

TRANSMUTATION of the elements, once the dream of the alchemists, is now being carried out as an everyday operation in the laboratory and on the industrial scale. The present situation and its implications, especially in so far as they concern chemistry, were reviewed in a group of three papers given before Section B (Chemistry) of the British Association at Liverpool on September 8.

In the introductory paper, Dr. R. Spence (Atomic Energy Research Establishment, Harwell) showed how transmutation is occurring continuously due to the radioactive decay of the naturally occurring radioactive elements on one hand and to the absorption of cosmic radiation by the atmosphere on the other. In the case of uranium minerals, in addition to the normal decay series the spontaneous fission of the isotope uranium-235 leads to the production of neutrons, some of which are captured by the uranium-238 isotope, which decays through neptunium-239 to plutonium. Seaborg and collaborators at the University of California have identified extremely small amounts of plutonium (~ 1 part in 10^{14}) in carnotite. Cosmic-ray neutrons react with the nitrogen of the atmosphere to give carbon-14 and to a smaller extent to give hydrogen-3. On the basis of data given by Libby and co-workers at the University of Chicago, it has been calculated that 16 mgm. of radiocarbon are produced in the earth's atmosphere every minute.

The development of particle accelerators and later of the chain-reacting pile has provided us with the means of bringing about transmutations on a comparatively large scale. If the construction of nuclear reactors for the generation of electrical power proceeds as might be expected, it is quite likely that at least one ton of fissile material will be consumed in Britain per annum by 1970. World consumption might conceivably be as much as 100 tons per annum by the end of the century. The long-term future is very much dependent, however, on the successful transmutation of naturally occurring thorium or naturally occurring uranium into the fissile isotopes uranium-233 and plutonium-239, respectively, on an industrial scale. In this way the whole of the natural uranium and thorium supplies could be utilized as nuclear fuel instead of less than 1 per cent of the natural uranium as at present.

Besides the isotopes uranium-233 and plutonium-239, other isotopes of the heavy elements are produced in nuclear reactors, such as neptunium-237, americium-241 and curium-242. These were discussed in more detail by Dr. R. Hurst in the last of the three papers of the symposium. Since fission of 100 tons of nuclear fuel yields about 100 tons of fission products it is important that some effort should be made to utilize this material. The fission products consist of isotopes of elements in the middle of the Periodic System, from zinc to gadolinium. Work is going on both in the United States and in Britain to develop uses for the radiation from fission products such as for the preservation of meat and other foods, for sterilization of pharmaceuticals, for production and treatment of plastics and for bringing about chemical reactions. The fission products also contain the elements technetium and promethium, which do not occur in Nature. It is conceivable that some use will be found for these elements in due course and also for the inert isotopes arising from total decay of the active species.

The second paper, given by Dr. K. Chackett (University of Birmingham), dealt with transmutation induced by accelerated particles. The Bohr theory of nuclear reactions forms a useful basis for understanding the nature of the products of such reactions and also how their yield varies as a function of the energy of the bombarding particle. The cyclotron has been commonly used for the production of radio isotopes by bombardment; but there are severe restrictions on the form of target material which can be used. For example, the heat transmitted to a small area of an internal target can amount to several kilowatts. This means that only high melting point metals can be used unless the beam intensity can be reduced well below the maximum available, and that some method of cooling may be needed. Liquids can be irradiated externally, but a window is required to admit the beam on account of the fact that cyclotrons have almost always been constructed to give horizontal radiation. Examples were quoted of isotopes which can be made by means of the 60-in. cyclotron which cannot be obtained from piles. As the product of the bombardment is usually an element different from the target element, it can generally be obtained 'carrier-free'.

Very recently, the University of Birmingham 60-in. cyclotron, in common with some other similar machines, has been used in novel ways for accelerating heavy ions such as $^{12}C^{6+}$, $^{13}C^{6+}$, $^{14}N^{6+}$, $^{15}N^{6+}$ and $^{16}O^{6+}$ to energies in the region of 100 MeV. At least twelve different radioactive species have been obtained, for example, from the bombardment of aluminium. It has been known since 1951 that bombardment of uranium with $^{12}C^{6+}$ ions yields isotopes of the heaviest known element, californium ($Z = 98$). One of the objects of the present work at Birmingham is to see whether this work may be extended by the use of heavier bombarding particles to the production of new elements beyond californium.

Present-day researches in nuclear physics are largely concerned with obtaining particles of higher energy than can be achieved with cyclotrons. The reactions induced by protons, deuterons and alpha-particles of several hundred MeV. given by the 184-in. synchrocyclotron at Berkeley have been studied by radiochemical means. In these reactions the bombarding particle ejects several particles from the target nucleus, a process known as spallation. A simple case appears to be the production of magnesium-28 by the reaction $^{30}Si(p,3p)^{28}Mg$. This magnesium isotope has a half-life of 22 hr. and might be a valuable tracer. Although, in general, high-energy machines are unsuitable for production of radioisotopes on account of the low beam current, the high-energy proton process has some advantages over the cyclotron in this particular instance.

Even higher energies are available from synchrotrons as opposed to synchrocyclotrons; thus the Birmingham proton synchrotron has recently been put into operation and gives protons up to 1,000 MeV. The main interest in particles of such extremely high energy is in the production of mesons; but there can be little doubt that results of radiochemical interest will also be obtained in spite of the much smaller beam currents given by such machines.

The final paper of the session was given by Dr. R. Hurst (Harwell). He pointed out that bombardment with high-energy charged particles yields at most only a few micrograms of product. It is only in the chain-reacting pile where very large quantities of neutrons can be generated and absorbed that transmutation can be brought about on a large scale. In addition to the production of plutonium in natural uranium piles, as described in the first paper, a number of isotopes of other heavy elements are produced although in much smaller quantities. For example, a long-lived isotope of neptunium (half-life 2×10^6 years) is produced by the reaction $^{238}U(n,2n)^{237}U \xrightarrow{\beta} {}^{237}Np$. A small quantity has been isolated at Harwell, and a sample containing a few milligrams was shown. Plutonium also absorbs neutrons and undergoes the following successive reactions: $^{239}Pu(n,\gamma)^{240}Pu(n,\gamma)^{241}Pu(n,\gamma)^{242}Pu$. These isotopes are all long-lived α-emitters except plutonium-241, which undergoes β-decay with short half-life to give americium-241, an isotope of element 95. So far, only a few hundred milligrams have been separated from plutonium. Americium can also be irradiated with neutrons to give americium-242, which decays by β-particle emission to give curium-242 (element 96), which has been isolated in milligram quantities.

The study of the chemistry of these elements has yielded results of considerable theoretical interest. From their place in the Periodic System it might have been expected that they would resemble the transition elements. In fact, the metals are base, not noble, the oxides are refractory, the halides are slightly volatile, and the ions tend to be simple rather than complex. The properties parallel, to some extent, those of the rare earths. Chemical studies, X-ray spectra, absorption spectra and determinations of magnetic susceptibilities all lend support to the theory that an inner $5f$ electron shell is being built up as one proceeds up the so-called actinide series, similar to the building up of the $4f$ shell in the case of the rare earths. The magnetic susceptibilities of a large number of compounds of the actinide elements have been determined at Harwell, and it has, in fact, been found that U^{IV}, Pu^{III}, Pu^{IV}, PuO_2^{++}, Am^{III} are paramagnetic ions obeying the Curie–Weiss law.

The solution chemistry of these elements is also of considerable interest and reaches the highest degree of complexity in the case of plutonium, where all four valence states (III, IV, V and VI) can co-exist in solution.

The mechanism and kinetics of the reactions between these various species have been worked out in considerable detail, but are not yet fully understood.

The possibility of the synthesis of still heavier elements, beyond californium, was mentioned in the second paper. Seaborg and collaborators at the University of California have made a systematic study of more than a hundred α-emitters in the heavy element region, and it is now possible to predict both chemical and radioactive properties of elements beyond californium with reasonable certainty. It is expected that $^{247}99$ will have a half-life of the order of days, and $^{249}100$ a half-life of perhaps a few hours. Chemical separation would, therefore, be possible; but the cross-sections for the formation of such isotopes as well as the presence of competing reactions become increasingly unfavourable.

As the atomic energy industry develops, supplies of the heavier actinide elements will increase and it is likely that new and unexpected uses for them will arise. A mixture of plutonium and beryllium, for example, provides a practically permanent source of neutrons without the troublesome γ-radiation which is emitted by radium–beryllium sources. Americium has an abundant 59-KeV. X-ray, and a few milligrams have already been used experimentally at Harwell as a special radiographic source.

R. SPENCE

IMPORTANCE OF TITANIUM AND ITS ALLOYS IN ENGINEERING

A PAPER entitled "Titanium—a Metal of Engineering Importance?" was read on September 8 by Major P. L. Teed before Section G (Engineering) at the recent British Association meeting in Liverpool. The paper provides a clear picture of the possibilities of this metal, titanium and its alloys, in engineering, particularly in the field of air transport. Approximate mechanical properties of commercially pure titanium and of its alloys are as follows:

	Commercially pure titanium	Titanium alloys
0·2 per cent proof stress	34 tons/sq. in.	36–71 tons/sq. in.
Ultimate stress	39 tons/sq. in.	49–90 tons/sq. in.
Elongation	23 per cent	19–6 per cent

As with alloy steels, the room-temperature notched-bar impact resistance of the titanium alloys tends to decrease with increase in tenacity. A wrought, commercially pure titanium bar may, at room temperature, have a Charpy notch-bar value exceeding 50 ft. lb., while that of many of the stronger alloys may not, under similar conditions, absorb as much as 10 ft. lb.

As regards fatigue, at room temperature and employing standard test-pieces that are unnotched, the resistance of titanium and its alloys is impressively high—there can be little doubt that on the basis of ten million reversals of stress, this exceeds 50 per cent of the ultimate static tensile stress of the material. With regard to notched specimens, however, a less happy report has to be made. The impression arising from the work which has been done is that the metal and its alloys are much more notch-sensitive than alloy steels of the same static strength. Further, there is some evidence to show that, as the stress concentration factor is increased, the endurance is reduced to a considerably greater extent than would be the case with steels having similar static mechanical properties.

Titanium alloys, like those of other metals, are heat-sensitive. Above 100° C. and under comparable conditions, they have better specific mechanical properties than the wrought aluminium alloys; but at temperatures in excess of 400° C. those of several ferrous and non-ferrous alloys are superior to the best of the titanium ones, and above 800° C. hydrogen, nitrogen, oxygen, steam, carbon monoxide and carbon dioxide react vigorously with the hot metal.

Before leaving the mechanical properties of the metal and of its alloys, one troublesome defect must be mentioned. Both have quite deplorable frictional properties, and the metal is inclined to 'pick up', not only on itself but also on any other on which it is rubbing. It is possible, however, that some type of surface finish may be discovered which will overcome this difficulty.

So far as the chemical properties of the materials are concerned, it is already clear, although further work is required in more than one direction, that titanium and its alloys are resistant to a remarkable degree. Since this applies to sea water, even at temperatures up to those experienced in a steam condenser, titanium is a material of very definite interest to the marine engineer.

At present, though not necessarily for all time, really satisfactory castings cannot be made in titanium or its alloys, since all the materials which have so far been used for the moulds have been found to be attacked in varying degrees by the molten metal. Even should this difficulty be solved, the production of such castings will still prove difficult. The molten metal combines with vigour with so many gases that special melting and casting techniques would appear to be essential.

This intense chemical activity requires that titanium and its alloys should be forged in the temperature-range 880–980° C., and again, unless the heating is carried out in an inert gas, scale will be formed, which tends to reduce the life of the dies. Some of the two-phase alloys are subject to marked grain growth, necessitating quicker heating and a heavy reduction per heat, while subsequent heat treatment to bring about phase transformations may also be beneficial. The hot extrusion of the materials, given suitable die lubrication, presents little technical difficulty, and one most interesting lubricant suitable for these metals is molten glass. Cold drawing, if the metal is covered with a thin film of scale, presents few difficulties; but if the scale coat is inadequate, pick-up will occur.

The welding of titanium and its alloys must be carried out under conditions which prevent chemical reaction between the hot, or molten, metal and the surrounding atmosphere, and the helium or argon arc becomes ideal. Due, however, to the surface embrittlement which results when the materials are heated in air, the whole of the hot metal must be enclosed in an inert atmosphere, inert gas being fed to both sides of the weld during the operation. With commercially pure titanium and with the single-phase alloys, such modified helium- or argon-arc techniques produce extremely good welds, having an ultimate tensile strength and ductility of the same order as that of the basis metal. In the case of the two-phase alloys, however, although the tensile strength of the weld is satisfactory, the ductility is normally disappointing.

The machining of these materials still presents difficulties, and the best tool materials, cutting speeds, lubrication, etc., are still far from being satisfactorily determined. Commercially pure titanium can be deep-drawn to about the same extent as a low-carbon steel, but more frequent annealing is required and lower press-speeds. With the alloys of titanium, greater difficulties are experienced as their tensile strength increases, but a comparatively small increase of temperature, say, to 250–350° C., will greatly facilitate the more difficult press operations.

The second half of Major Teed's paper was devoted to a detailed consideration of the effect of the substitution of titanium in appropriate aircraft parts. Despite the high cost of the metal, varying from £3·5/lb. for hot rolled rods to £5·3/lb. for annealed sheet, its high mechanical properties and relatively low density suggest that by such 'titanizing' the disposable load of a machine at present having a basic equipped weight of 70,000 lb. could be increased by about 1,550 lb. or, alternatively, that in the design of an aircraft with a given disposable load such uses of titanium would result in a slightly smaller machine with certain ancillary advantages.

In Major Teed's view the question contained in the title of his paper—even at its present price—can be answered in the affirmative. Titanium and its alloys will have applications in mechanical, aeronautical and, possibly, marine engineering, and, as the price falls, the field of utility will surely widen.

KUMASI COLLEGE OF TECHNOLOGY, GOLD COAST

By Dr. J. P. ANDREWS

Principal of the College

THE Kumasi College is one of those Colonial regional colleges the development of which is fostered by the Advisory Committee for Colonial Colleges of Arts, Science and Technology. It came into legal being on October 6, 1951, provided with a mercifully amplified name. Development since then has been rapid, and 430 students were in residence in June 1953. This number is expected to rise to more than 700 by January 1954.

The site of the College is a tract of tropical forest about four miles from Kumasi, the capital of Ashanti. It was acquired through the generosity of the Asantehene, Sir Osei Agyeman Prempeh II, and consists of about four square miles of small hills and valleys, originally hidden in dense jungle.

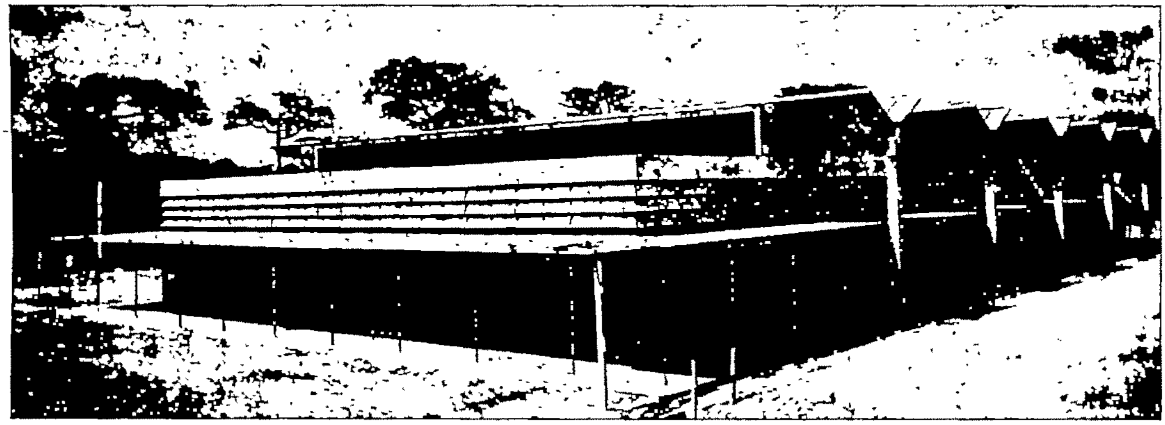
The College began with the transfer to the new site at Kumasi of the Achimota Teacher Training College, under its rector, Lord Hemingford, who became the first head of the Teacher Training Department of the new College. For this transfer a considerable area was cleared, and a large number of frame buildings of prefabricated type was erected during 1951, thus enabling the new College to open in January 1952 with some two hundred teacher-training students in residence, with the appropriate organization.

During the eighteen months since then, major buildings, designed by Messrs. Cubitt, Scott and Partners, have been under construction and are nearing completion. Indeed, the first section of the engineering workshops has been in use for instructional purposes since November 1952. The completion of the workshops, of the School of Pharmacy, and of a classroom block is anticipated this autumn. Houses for teaching staff have been constructed.

A major effort, with the expenditure of large funds on buildings and new equipment, has been made in the direction of engineering. The proposal is to run four-year courses in civil, mechanical and electrical engineering, courses in building (two years) and a course in surveying in preparation for the intermediate examination of the Royal Institution of Chartered Surveyors. Some twenty students distributed between the three branches of engineering have already completed one session. The objective in these courses is ultimately the graduate qualification of the professional institutions, negotiations with which have met with helpful response. A College diploma will also be available. It is possible that at a later stage permission will be sought to take the external degree of B.Sc. of the University of London; but the real need of the country at present is for training with a strong bias to the practical rather than the academic side of engineering. One of the greatest obstacles in the early years of training lies in the absence of the familiarity with mechanical things and ideas which an English boy acquires so readily. The first two years of the engineering courses therefore seek to supply the basic scientific knowledge and some familiarity with mechanical matters. The students enter after passing School Certificate, and wherever possible some experience in engineering or allied employment is demanded of the entrant. The staff of the department is being built up, and new machinery is flowing in and being installed. Prospects of the early completion of a well-equipped department, admirably housed and properly staffed, are excellent.

The staff and equipment of the School of Pharmacy, now operating in temporary quarters, were transferred from the Accra Hospital at Korle Bu, and when installed in the new building will be comparable with similar departments to be found in Britain. Pharmacy is a popular subject in West Africa; but so far, standards have been considerably lower than those in Britain. The Gold Coast Pharmacy and Poisons Board has recently taken steps towards improvement. One of these steps is the recognition of the College four-year course.

In addition to teacher training, engineering and pharmacy, Departments of Commerce and Agriculture have been set up, and already have students. In commerce the chief courses are accountancy and secretarial, covering the requirements of the chief accountancy bodies and of the Chartered Institute of Secretaries. The Agriculture Department is in the delicate position of being one of three bodies in the Gold Coast which provide training, namely, the Government Department of Agriculture, the Department of Agriculture of the University College of the Gold Coast, and the parallel department of the Kumasi College. By general agreement the functions of Kumasi College will be to train teachers of rural science, to give basic agricultural science to students in the Government Training School, and to carry out



The first section of the engineering workshops of the Kumasi College of Technology research on the production of soft food crops—a species of market-gardening which has been much neglected in the Gold Coast. In addition, a course of one year's duration is given to train instructors of mechanized agriculture.

A further department, in some respects foreign to the ultimate purpose of the College, is called the Department of Intermediate Studies. This Department was organized initially, at the request of the Government, to fill the gap left by the absence of a sixth form in a number of secondary schools. The students in the Department read for Higher School Certificate, both in arts and science; and the majority of them apply for entrance to the University College. The Department fulfils, however, the further function of providing basic science for students of pharmacy, engineering and agriculture.

All students in the College at present spend some of their time in studying English, and a large proportion take mathematics. A Department of Mathematics and an organization under a senior lecturer in English have therefore been set up. Students, teaching staff and many of the administrative staff are resident on the compound. It follows that when the student population exceeds a thousand, with perhaps a hundred teaching staff and a large population of administrative and estate employees, the College will amount to a small town, with its own services, electricity, water, gas, its own roads and transport system. Already the pre-occupations of the administration tend to resemble those of a small town council.

Continued progress at the present rate is unlikely, but may still be rapid. It is a question whether funds from the Gold Coast Government will be forthcoming in satisfactory amount for a sufficient length of time. The shortcomings of the Ordinance, which appears to have been modelled on that of Achimota School, are beginning to be felt. Autonomy, which is incorporated in the Ordinance, tends to be nullified by the close dependence on funds provided by the Government, and the absence, as yet, of a quinquennial or triennial grant. Nevertheless, the essentials of a great College already exist, with far-reaching effects on the prospects for successful self-government in the Gold Coast.

OBITUARIES

Dr. Colin Campbell

DR. COLIN CAMPBELL, dean of the Faculty of Science and assistant director of the Chemical Laboratories in the University of Manchester, died at his home on August 23. He entered the University, in which he spent his whole career, from William Hulme's Grammar School, Manchester, in 1906 and, after graduating with first-class honours in chemistry, was appointed Schunck research assistant to Prof. H. B. Dixon, with whom he published accounts of investigations on the velocities of explosions in gases, and on the velocity of sound in, and the specific heats of, gases at high temperatures.

During the First World War, Campbell was a member of Dixon's team of inspectors of explosives under the Ministry of Munitions. Afterwards, with a succession of collaborators, using mainly photographic methods, he continued to study the velocities of gaseous explosions with particular reference to the changes arising as explosions pass from one tube to another of different diameter or through successive tubes of glass and rubber, to the influence of dilution by inert gases and also to the initiation of explosion in one gaseous mixture by an explosive wave from another. Many of these investigations involved ingenious developments of technique, as did his work on the determination of pressures developed in the combustion of gaseous mixtures; but perhaps the most elegant experimental work followed the observation, with D. W. Woodhead, of striations in the photographic records of explosion waves in carbon monoxide–oxygen mixtures (1926). Campbell and Woodhead carefully investigated this phenomenon, and Campbell and A. C. Finch, two years later, established that it is accounted for by the helical path followed by these explosions in a tube.

Dr. Campbell became a member of the staff of the Chemistry Department in the University of Manchester in 1914 and senior lecturer in 1925. He played an important part in the teaching in the Chemistry Department, and his experimental lectures, characteristic of his personal qualities, were models of lucidity and precision. He was in continual demand as a lecturer to more general audiences outside the University. Many generations of students quickly came to value his skilful and patient teaching in the first-year laboratory.

As assistant director of the Chemical Laboratories from 1935 his activities embraced a much wider field. His influence in maintaining a unified department, through a period of considerable change, cannot be over-estimated. He was the faithful guardian of a great departmental tradition. Eminently approachable, his friendly manner and spontaneous interest gained him the confidence of both colleagues and students, with whom he established close personal contacts. He was usually the first to learn of a student's personal problems, and those in difficulty, including disappointed examinees, were always certain to receive sympathy and encouragement to further effort. The meeting of the University Chemical Society last year, at which he gave his presidential address reviewing the history of the Department, was a memorable occasion. He was an influential member of the Board of the Faculty of Science for many years and was appointed dean in 1952.

Manchester's religious life will be greatly impoverished by his death. He gave a life-time of devotion to the Congregational Church in the area, to the Manchester and Salford Shaftesbury Society and particularly to his own Cavendish Congregational Chapel, of which he was secretary, Sunday school superintendent and often organist.

Colin Campbell will be sadly missed in his University and in many walks of life outside its walls; but he leaves behind indelible and happy memories of his deep and sincere Christianity, strong human sympathy, warm friendliness, modesty and wise patience. It is as an unfailing friend that so many will continue to think of him.

E. R. H. JONES
G. NORMAN BURKHARDT

WE regret to announce the following deaths:

Prof. A. F. Holleman, formerly professor of chemistry in the Universities of Groningen and Amsterdam, on August 11, aged ninety-three.

Dr. E. P. Hubble, of Mount Wilson Observatory, associate of the Royal Astronomical Society, on September 28, aged sixty-three.

NEWS and VIEWS

Chemistry at Durham :

Prof. F. A. Paneth, F.R.S.

Prof. F. A. Paneth, on reaching the retiring age this autumn, terminates his highly successful activities as professor of chemistry and first director of the Londonderry Laboratory for Radiochemistry in the University of Durham, and is going to Mainz as director at the Max Planck Institute for Chemistry. In the early years of this century, Sir William Ramsay addressed an audience in Vienna. The large and enthusiastic gathering listening to his fascinating report of the discovery of the noble gases included the great landowner Kuppelwieser, who was so much impressed by Ramsay's lecture that he decided to finance the costs of an institute for radioactive research to be erected by the Vienna Academy of Sciences. Paneth, who had just taken his degree in chemistry in the University of Vienna, joined this institute as an assistant and contributed very materially to the important work carried out in the course of the first decade of its activities. This included numerous pioneer investigations on the application of radioactive indicators in inorganic and physical chemistry. In 1913 Paneth spent some time in Soddy's laboratory in the University of Glasgow, where one of his activities was the study of methods of microanalysis of gases which he later developed to a most remarkable extent. The first fruit of his great skill in analysis of gases was the discovery of polonium hydride, followed by the discovery of lead, bismuth and tin hydrides and of free organic radicals. In recent years he has made very important contributions to our knowledge of the composition of the higher atmosphere and of the helium content of meteorites as an indication of their age. Simultaneously, he has promoted several branches of radiochemistry.

Intense and most successful occupation with numerous experimental problems did not prevent Paneth from being a most effective first president of the International Commission of Radioactivity. Nor did it prevent him from showing much interest in the definition of fundamental concepts of chemistry and in the study of the history of science. This is witnessed by his publications on the life and works of Boyle and his remarkable lecture on Thomas Wright of Durham and Immanuel Kant. Prof. Paneth has shown himself to be an ingenious experimenter, a scholar and an eminent teacher.

Prof. G. E. Coates

Prof. Paneth is being succeeded at Durham by Geoffrey Edward Coates, son of J. E. Coates, the retired professor of chemistry in the University College of Swansea (University of Wales). Prof. Coates, who was born in 1917, was educated at Clifton College and Queen's College, Oxford, where he obtained the degrees of B.A. (first-class honours in chemistry) and B.Sc. During the Second World War he did research work on corrosion at the Metallurgical Research Laboratories of the Magnesium Metal Corporation, Swansea. Since 1945 he has been lecturer in inorganic chemistry in the University of Bristol; he has acted also as chief examiner in chemistry to the Bristol University School Examination Board. In December 1952 he was appointed senior reporter for inorganic chemistry for the "Annual Reports of the Chemical Society", and for the past five years he has been consultant to the Imperial Smelting Corporation, Ltd., Avonmouth. He is also a member of the Bond Energy Committee and the Fuel Incendiary Panel (Ministry of Supply, Scientific Advisory Council). Prof. Coates's publications before the War dealt with electrochemical problems: the electrolytic corrosion of metals, electrode potentials, and polarization; but some were also concerned with questions of molecular structure. Since the War, he has devoted his efforts mainly to the study of organometallic compounds (for example, trimethylgallium and dimethylberyllium), of borine derivatives, and of fluorine compounds.

E. R. Cooper Memorial Award for Work in New Zealand

In memory of the late Dr. E. R. Cooper, a fund is being raised to institute an annual award to scientific workers. Dr. Cooper, who died a year ago at the age of forty-two, was one of New Zealand's younger scientists. His death was a serious loss to scientific research, organization and administration. For a decade he guided the development of the Dominion Physical Laboratory, which, beginning with a very small physics section, became under his directorship the largest branch of the N.Z. Department of Scientific and Industrial Research. Besides his capacity as an organizer, he possessed outstanding scientific qualities. He always attached great importance to the publication of scientific work and the development of the natural resources of New Zealand. These two ideas have been incorporated in a memorial award sponsored by the Dominion Physical Laboratory Technical Advisory Committee of the Council of Scientific and Industrial Research, and the Department of Scientific and Industrial Research, New Zealand. The award will be made annually to the author or authors of published physics or engineering papers who give the best account of their research work in New Zealand, preference being given to work that contributes to the development of the natural resources of that country. The Royal Society of New Zealand will administer the award, and will appoint a selection committee consisting of two representatives of the University and two of the Royal Society of New Zealand, and one of the Department of Scientific and Industrial Research. Donations towards the capital sum required to establish the award should be sent to the Secretary, D.S.I.R., P.O. Box 8018, Government Buildings, Wellington. While the monetary value of the award will be small, its scientific standing will be high and in accord with the high standard set by the scientist whose memory it perpetuates.

Commonwealth Fund Fellowships for Advanced Study and Travel in the United States

A number of Commonwealth Fund Fellowships are again being offered by the Commonwealth Fund of New York to British subjects for study and travel in the United States. All expenses of travel, study and living will be met, with some adjustment of stipends for married men. The Fellowships, which are open to British men and women who are not normally resident in or near the Americas and who have not previously worked or studied for more than a few months in the United States, are offered annually in six categories as follows. *General*: twenty Fellowships to graduates of a university in Great Britain and Northern Ireland; candidates must be available in London for interview in March 1954; age 23–32; tenure, 12–21 months; applications by December 15. *Home Civil Service:* five fellowships to permanent members in the higher ranks of the Civil Service in Great Britain, three for the administrative grades and two for the scientific and professional grades; age, less than 40; tenure, 6–12 months; applications by December 31. *Dominion Civil Service:* five fellowships to Civil servants in the Governments of Australia and New Zealand; age less than 40; tenure, 9–15 months; applications by November 1. *Colonial Civil Service:* two Fellowships to Civil servants in the Governments of British Colonies, Protectorates and Trust Territories; age, less than 40; tenure, 6–12 months; applications by November 16. *Journalism:* three fellowships to journalists, practising in the United Kingdom and engaged on the opinion-making or broadly editorial side of their profession; age, 23–35; tenure, 9–15 months; applications by December 31. *American Studies:* four Fellowships to faculty members appointed to or holding posts in American studies in universities in the United Kingdom; candidates to be nominated by their universities; tenure, 4–12 months (these Fellowships are not limited by previous study in the United States). Application forms and further details of these Fellowships can be obtained through British universities or through Government departments, or from the Warden, Harkness House, 35 Portman Square, London, W.1.

Controlled Leaf Morphogenesis

By growing plants of *Marsilea* in aseptic culture media of known composition, A. Allsopp (*Ann. Bot.*, N.S., **17**, 65, 37; 1953) has shown that the leaf shape can be controlled. In plants with the characteristic tetrafid adult leaves, reversion to simple bifid or awl-shaped juvenile leaves was obtained by depriving the cultures of either sugar or mineral nutrients. There was also a concomitant reduction of the solenostele to a protostele. Comparable results were obtained by using the excised apices of rhizomes or their lateral branches. These results are of particular interest in relation to the general problem of heteroblastic leaf development—a phenomenon originally attributed by Goebel to nutritional factors but variously ascribed to other causes by different investigators. The main body of evidence supports Goebel's view; but the precise relation of nutrition to the regulated ontogenetic pattern of leaf development has never been elucidated. In a discussion of this problem, reference is made to the changing dimensions of the shoot apical meristem during the normal ontogenetic enlargement and under 'starvation' conditions. In most cases of heteroblastic development it is unnecessary to seek explanations in terms of special growth substances, physiological ageing, etc. In the individual plant the changing size of the apex under the influence of nutritional factors would seem to afford an adequate explanation.

The *Luffa* Plant and its Uses

The loofah of commerce, also known as the '*Luffa* sponge', 'dishcloth' or 'dishrag gourd', 'snake gourd' and 'vegetable sponge', is the cleaned, dried inner fibrous tissue of the fruit or gourd of *Luffa* spp., which grow readily in most warm countries. It is a climbing annual plant, and has been grown in Japan from olden times. The plant and fruits resemble cucumbers; but the fruits are fatter and hang heavily on the vines, while the stems are more woody and stronger. In Japan, the plant blooms during June–July, and the flowers last well into the autumn. The two most common species are *Luffa cylindrica*, to which belong the varieties cultivated in Japan for loofah production, and *L. acutangula*. Both species produce good fibre; but with *L. cylindrica* the fruits are bigger and more cylindrical in shape, and the fibres are of better quality. The best type of loofah for the commercial market is the one produced in Japan, where the soil and climate have proved well suited to their cultivation. An account of the loofah industry in Japan has been given by J. S. Ingram in *Colonial Plant and Animal Products* (**3**, No. 2). The cultivation and possibilities of the plant in Colonial territories is also described.

Bird Preservation

In 1950 a conference was held in Paris to discuss the revision of the international convention for the protection of birds useful to agriculture, which had been signed in 1902. The conference was attended by delegates from Austria, Belgium, Denmark, France, Greece, Netherlands, Portugal, Spain, Sweden, Switzerland, Turkey and the United Kingdom and, on behalf of their Governments, a new draft convention was signed *ad referendum* by all delegates. The full text of the convention is set out in the sixth bulletin of the International Committee for Bird Preservation, which has been prepared with sections in English, German and Spanish and may be obtained from the British Museum (Natural History), Cromwell Road, London, S.W.7. Besides the usual reports on bird protection in various countries, the bulletin also reviews the work of the International Wild Fowl Research Institute and gives full details of the legislation which has been adopted by member countries for the better preservation of wild fowl.

Philosophy for Management

A valuable guide for members of its supervisory staff has recently been issued by the Triplex Safety Glass Co., Ltd. The supervisory staff is taken to include the directors, senior staff and foremen; and, in a foreword, the chairman and managing director, Sir Graham Cunningham, suggests that the booklet will help them to become clear about the policy of the Company and about the human relationships involved in it. The booklet includes a chart showing the organization of the Triplex Group and short explanatory statements on such topics as the function of the board of directors, research and development, the meaning of profit, the reasons for the use of specialist departments, the role of the trade unions, the structure of wages, the value of suggestion schemes, accident prevention and personnel services. The booklet is written in a succinct and admirable manner, and the ideas contained in it might well be copied for use in other firms.

Endeavour

In the eleven years since it was first published by Imperial Chemical Industries, Ltd., the quality of the contributions to *Endeavour* has been at a consistently high level. It is doubtful whether any previous issue, however, could equal the quality of the articles appearing in the July issue of this journal. W. B. Alexander, for example, has written an admirable article on ornithological illustration which is supported by coloured plates of first-rate quality. In another article Sir Henry Dale discusses the transmission of impulses along muscle and nerve fibres and analyses the objections to theories of electrical conduction across cell-junctions. Dr. W. G. Palmer considers the basis of stereochemistry and its application to inorganic compounds, while Dr. D. Mackie contributes a useful biographical account of the French chemist who taught Lavoisier, Guillaume-François Rouelle. In an article on the evolution of adaptations, Prof. C. H. Waddington puts forward a hypothesis to explain how acquired characteristics may become hereditarily fixed by a process of genetic assimilation not invoking the generally discredited theory of direct inheritance. Prof. K. Mather examines the contribution of biometry to the growth of the inductive method, while B. W. Mott deals with progress in metallurgical microscopy. An interesting feature of this issue of *Endeavour* is the personal message of goodwill from the Duke of Edinburgh.

Directory of Sources of Specialized Information in Great Britain and Ireland

The "Aslib Directory", published in 1928, was for many years the standard work on sources of specialized information in Great Britain and Ireland. It has been out of print for a number of years, and a new edition is now in course of preparation. The "Directory" should prove of great value to research workers and others in giving details of the chief collections of books and other material on specialized subjects and where they can be obtained. To cover as wide a field as possible, more than six thousand questionnaires have been sent to universities, colleges, technical institutions, public libraries, museums, research organizations, government departments, learned and specialist societies and commercial and industrial firms. Inevitably, some organizations which act as sources of information on certain specialized subjects may have been overlooked, and if they consider that they have a claim to be included in the "Directory", they should get in touch as soon as possible with the Director of Aslib, 4 Palace Gate, London, W.8.

National Science Foundation: Completion of Research Awards for 1953

The National Science Foundation has announced the award of thirty-four research grants, amounting to about 208,000 dollars, which complete the total of grants made by the Foundation during the fiscal year 1953 for the support of basic research and related matters. During the year, the Foundation has made 292 awards totalling more than 2,151,000 dollars, and since the beginning of the programme in 1950 more than four hundred such awards have been made, totalling about 3,635,000 dollars. The fields included in the latest list are chemistry, earth sciences, environmental biology, genetic biology, molecular biology, regulatory biology, systematic biology, scientific information, scientific personnel information, and special studies in science. The duration of research grants in this group ranges from one to two years, with an average length of 1·3 years.

Rajasthan Academy of Sciences: Officers for 1953–54

At the third annual meeting of the Rajasthan Academy of Sciences, the following officers were elected for the session 1953–54: *President*, Dr. P. Nilakantan, principal, Birla College, Pilani; *Vice-Presidents*, Dr. K. M. Gupta, professor of botany, Jaswant College, Jodpur, and Dr. A. K. Chatterji, vice-principal, Engineering College, Pilani; *Vice-Presidents* (who have held the office of president), Prof. M. L. Schroff, Calcutta, Dr. M. L. Roonwal, Dehra Dun, and Dr. G. S. Mahajani, Delhi; *Secretary*, Prof. K. Ramamurti, Rajasthan Academy of Sciences, Pilani, Rajasthan; and *Treasurer*, Shri. Roshan Singh.

International Union of Crystallography, 1954

As already announced, the Third General Assembly and International Congress of the International Union of Crystallography will be held in Paris during July 21–28, 1954. At the Congress, papers will be presented on all aspects of crystallographic research; there will also be an exhibition of crystallographic apparatus and books. After the Congress two specialized symposia will be held on "The Location and Function of Hydrogen" and "The Mechanism of Phase Transitions in Crystals", and there will be visits to localities of mineralogical interest. Full details of the meeting may be obtained from the General Secretary of the Union (R. C. Evans, Crystallographic Laboratory, Cavendish Laboratory, Cambridge, England), from the Secretary of the Programme Committee (A. J. Rose, Laboratoire de Minéralogie, 1 rue Victor Cousin, Paris 5, France) or from any of the following regional representatives of the Programme Committee: G. Menzer (Universitätsinstitut für Kristallographie und Mineralogie, Luisenstrasse 37/II, München 2, Germany), W. H. Taylor (Crystallographic Laboratory, Cavendish Laboratory, Cambridge, England), J. D. H. Donnay (The Johns Hopkins University, Baltimore, Maryland, U.S.A.). Offers of papers for the Congress and symposia and notice of enrolment must reach the secretary of the Programme Committee (preferably on the form accompanying the first circular) by February 15, 1954. All general correspondence should also be addressed to the Secretary of the Programme Committee.

Announcements

Mr. W. J. C. Lawrence has been made acting director of the John Innes Horticultural Institution as from October 1, when the former director, Dr. C. D. Darlington, took up his post as Sherardian professor of botany in the University of Oxford (*Nature*, 171, 373; 1953).

Dr. R. Holroyd, a director of Imperial Chemical Industries, Ltd., will deliver the second Coal Science Lecture of the British Coal Utilisation Research Association on October 21 at 4.0 p.m. in the rooms of the Royal Society. He will speak on "Coal as a Source of Chemical Raw Material".

The University of Chicago is offering three post-doctoral fellowships in statistics, worth 4,000 dollars, for the academic year 1954–55. The purpose of the fellowships, which represent the fourth year of a five-year programme supported by the Rockefeller Foundation, is to give established research workers in the biological, physical and social sciences the necessary training in modern statistical analysis for the planning of experiments and other investigations and in the analysis of empirical data. Further details pertaining to applications for these fellowships (which must be completed by February 15, 1954) can be obtained from the Committee on Statistics, University, Chicago 37.

ANALYSERS AND COMPUTERS FOR ELECTRICAL SYSTEMS

A VACATION school on analysers and computers for electrical systems was held in the Electrical Engineering Department of the Imperial College of Science and Technology, London, during the week July 13–17, and was attended by some sixty engineers drawn from industry, the British Electricity Authority, research associations, technical colleges and the universities. The purpose of the school was to encourage the wider use by electrical engineers of analysers and computers for solving the problems that arise in the fields of electrical machines, electrical control systems and power networks. In an opening address, Mr. F. J. Lane, transmission design engineer to the British Electricity Authority, stressed the value of vacation schools in providing opportunity for discussion and exchange of information, and referred to the continuing development of more accurate methods of calculating the design and performance of electrical systems.

The first lecture was by Mr. B. Adkins, of Imperial College, who described the course as an opportunity for electrical engineers to review recent improvements in the methods available for the solution of numerical problems with the aid of computers, analysers and models. He went on to discuss electrical machine problems, grouping these as design calculations and performance calculations, each group comprising routine calculations and research investigations, and showed some examples of each type. In the following lecture, Dr. J. R. Mortlock, of British Thomson-Houston Co., Ltd., Willesden, introduced some of the more common problems met in the design of power systems, showing the types of equation encountered in each and the usual methods of solving them. The third lecture, by Dr. J. H. Westcott, of Imperial College, dealt with the design of closed-loop control systems. A discussion of steady-state calculations and graphical methods using harmonic responses was followed by a survey of methods of estimating transient response with suggestions for applying more comprehensive criteria to the performance, and hence design, of control systems.

Dr. W. J. Gibbs, of British Thomson-Houston Co., Ltd., Rugby, opened the next section of the course with a lecture on the mathematics of the problems. He showed that problems first require formulation by the specification of an ideal system which can be represented in mathematical terms, and then reviewed the types of calculation often required. He demonstrated that matrices can assist the orderly arrangement and manipulation of performance equations of all types of system. The remaining lectures dealt with methods for solving equations of the types described by Dr. Gibbs.

In a lecture on "Systematic Computation", Mr. M. W. Humphrey Davies, of Imperial College, put forward suggestions for processes intermediate between simple slide-rule calculations and the complex methods used in automatic computers. After surveying existing types of hand-operated calculating machines, he demonstrated a convenient method for the solution of sets of linear simultaneous equations, and described an improved type of semi-automatic machine, designed for handling two-dimensional quantities, that is being constructed at Imperial College. He concluded by suggesting that semi-automatic machines might be specially suitable for many routine calculations.

On the evening of July 14 members of the school visited the laboratories at Imperial College and saw the automatic digital computers constructed by Dr. Tocher in the Mathematics Department and a transformer-analogue analyser, a semi-automatic decimal computer for complex quantities and other analogue devices in the Electrical Engineering Department. July 15 was spent at the National Physical Laboratory seeing the automatic computer (known as the ACE), the analogue differential analyser and the punched-card tabulating equipment in the Mathematics Division and an analogue device for the design of control systems in the Servo-mechanisms Laboratory.

Dr. J. M. Bennett, of Ferranti, Ltd., described several types of automatic digital computer and discussed the advantages of their rapidity and accuracy in dealing with different types of engineering problem. The lecture concluded with details of the method of handling typical problems. Mr. L. Gosland, of the Electrical Research Association, in a lecture on "Analogue Analysers" gave an extensive survey of analogue computers, network analysers, models and simulators, giving examples of their application to practical problems.

The final lecture, by Dr. G. R. Slemon, of Imperial College, was concerned with the solution of non-linear problems, confining itself to two methods of considerable generality: namely, numerical or step-by-step methods, and approximate steady-state methods using modified linear techniques. Finite difference methods were described for the solution of first-order, simultaneous and higher-order differential equations with variable parameters. Dr. Slemon then explained his 'fundamental frequency' approach to steady-state non-linear circuits and showed how this could be applied to both power-frequency and stability problems. Finally, adaptations of mathematical, graphical and other techniques for use with the fundamental-frequency method were surveyed.

The discussions that followed the various lectures and the general discussion at the end of the course showed that the vacation school had provided a useful meeting-ground for experts in various types of electrical design problems who had been able to exchange useful information concerning developments in the use of analogues and computers. It appeared that there would be considerable demand for the facilities of automatic computing machines as these become available and that there is scope for improvements in desk machines. It was felt that a desk computer with a trained operator would be a useful adjunct to many engineering offices, but that analogue rather than digital devices would often be preferred by engineers because explicit mathematical formulation of the problem is unnecessary and because such devices are frequently analogous to the physical system, with the added advantage in power network and similar problems that the general behaviour of the system can be observed directly. Such devices make it possible for the engineer to solve his own problems with only occasional assistance from a mathematician, and this was thought to be preferable to the use of external computing services.

MICROWAVE OPTICS

WITHIN the past two decades much research has been carried out on electromagnetic radiation of wave-lengths which belong to the transition region between the ordinary radio region and the optical region of the electromagnetic spectrum. Because of certain properties characteristic of this range, and also because the wave-lengths in this transition range are of the order of magnitude of most mechanical devices handled in laboratories, this new branch of electromagnetic theory, often called microwave optics, offers to physicists many interesting new opportunities. These are being well explored, for example, in connexion with communications and radar.

During the four days June 22–25, a symposium on microwave optics was held at McGill University, Montreal, under the joint sponsorship of the Eaton Electronic Research Laboratory, of Commission VI of the International Scientific Radio Union (U.R.S.I.) in Canada and the United States, and of the Electronic Research Directorate, Air Force Cambridge Research Center (U.S.A.). The symposium marked the scientific opening of the Eaton Electronic Research Laboratory, which now, in its third year of existence, is already playing a prominent part in this field of research, under the directorship of Prof. G. A. Woonton.

The main aim of the symposium was to bring together scientists who work not only on microwave optics but also on related subjects, such as light optics, information theory, operational methods, etc., thus enabling exchange of information and a closer collaboration between research workers in these fields.

The symposium was attended by about 140 scientists mainly from Canada and the United States and by seven guest speakers from Europe. During the four days, altogether sixty-four papers dealing with a wide range of subjects were presented. These numbers themselves indicate the great interest now shown in microwave optics. There were altogether eight half-day sessions on the following subjects: scattering (two sessions); microwave optical systems and aberrations; electromagnetic diffraction (two sessions); electromagnetism and diffraction; Fourier transforms and information theory; radio lenses, and other topics of special interest. In addition, there was a round-table conference on Fourier transforms, under the chairmanship of Dr. Roy C. Spencer, of the Air Force Cambridge Research Center. It is impossible in a short article to analyse the very extensive material presented at the symposium, and consequently only a brief account of the main subjects discussed will be given.

Papers presented in the session on scattering were mainly concerned with power series solutions of scattering problems, and with calculations and measurements of scattering cross-sections and radar cross-sections. Some integral-equation techniques were also described and applied to problems of diffraction by spheres, cones and wedges, subject to simple boundary conditions.

The session on microwave optical systems and aberrations began with a survey of some of the research carried out at the Naval Research Laboratory in Washington, and described investigations on microwave optical systems for use in radar scanning antennæ. Other papers were concerned with wide-angle focusing properties of paraboloidal mirrors, with applications of Rayleigh's tolerance criteria to microwave systems, and with the behaviour of the geometrical field near caustics. The ideal lens of Luneberg and its variants were discussed by several speakers in this session and also in the session on radio lenses. An interesting contribution to aberration theory was made in a paper concerned with characteristic curves in the image space, where a method was proposed for the derivation of functions orthogonal over parabolic and other domains; these should prove useful in certain theoretical investigations of diffraction.

In the session on radio lenses and other topics of special interest, an interesting account was given of some of the current researches carried out at the Ministry of Supply Telecommunication Research Establishment in Great Malvern; it dealt mainly with the use of optical techniques at millimetre wave-lengths. Several papers discussed the behaviour of various artificial dielectrics.

The papers presented in the two sessions just mentioned indicated the similarity as well as the differences between systems employed in microwave optics and in light optics: microwave systems work as a rule with a smaller number of surfaces and larger numerical apertures; in microwave optics aspherical surfaces and asymmetrical combinations are the rule; in light optics they are the exception. In systems working with ordinary light the illumination is, as a rule, uniform; in microwave systems it is usually tapered.

Electromagnetism and especially electromagnetic diffraction were particularly well represented. Many of the contributions dealt with various aspects of diffraction by apertures in plane screens, and were followed by lively discussions. The theoretical papers were mainly concerned with approximate methods of solution, while those dealing with the experimental aspects described methods and results of measurements of diffraction fields. The literature of diffraction by apertures in plane screens is very extensive, and the comments from the audience indicated the difficulties faced by all but the experts on this class of problems when trying to assess the merits of the various methods of solution and the present state of knowledge in this field. The present writer shares the view expressed by some of the scientists taking part in the discussion, that a formal solution to a diffraction problem is often of relatively little value unless supplemented by computational data, and that a good deal more effort ought to be devoted to this end. (In this connexion it may be of some interest to mention that although Sommerfeld's classical solution of the half-plane problem was obtained as early as 1896 and numerous discussions of this problem have been published since, it was not until 1952 that detailed diagrams were given, showing the behaviour of the amplitude and phase and of the energy flow (Poynting vector) in the neighbourhood of the diffracting edge (W. Braunbek and G. Laukien, *Optik*, 9, 174 (1952).; the diagrams bring out interesting features not previously suspected.)

Other papers dealt with asymptotic solutions (for large wave-numbers) of linear partial differential equations, with a new method (called 'cliff method') for approximate integration, and with the application of operational techniques to the development of diffraction integrals. Another group of papers was concerned with scalar treatment of diffraction problems and with the analogies between the field of geometrical optics and certain diffraction fields. A generalization of Fermat's Principle was suggested in a paper entitled "The Geometrical Theory of Diffraction". A good deal of attention was given to a paper concerned with the 'creeping wave' in the theory of diffraction. It outlined a method for problems concerned with the diffraction by objects not larger than about a hundred wave-lengths; the asymptotic expansions can then no longer be used, as there may be a considerable contribution from a wave creeping around the back of the object.

As already mentioned, one session was devoted to Fourier transforms and information theory. Accounts of useful Fourier and operational techniques were given and various applications described. Some analogies between optics and information theory were noted. This session as well as the round-table conference on Fourier transforms suggest that Fourier transforms and information theory are likely to play an increasingly important part both in light and microwave optics.

On several occasions during the symposium, attention was directed to investigations in related subjects closely analogous to the work described, and it became apparent that there is a good deal of overlapping and repetition in the two main fields. But no one who was present in the crowded sessions at McGill could have departed without being stimulated by the variety of ideas and by the impressive record of work carried out in microwave optics during the past few years. The only criticism which may be raised refers to the fact that each speaker was allowed only 10–15 minutes, a period certainly not sufficient for the presentation of some of the subjects. It is, however, easy to understand the difficulties with which the organizers of any large scientific gathering are faced in this connexion. To some extent these difficulties were overcome at McGill by the distribution, prior to the opening session, of mimeographed volumes containing summaries of all the papers. An extended version of these volumes will shortly appear as a special issue of the *Canadian Journal of Physics* and will undoubtedly become an important contribution to the literature on microwave optics.

CENSUS OF WOODLAND AREAS LESS THAN FIVE ACRES IN GREAT BRITAIN

THE first report of the census of woodlands in Great Britain, carried out during 1947–49, gave the statistics for the area and stocking of woodlands of five acres and more (see *Nature*, August 8, p. 240). The second report, which has now been published*, provides the additional data, collected during 1950–51, and completes the census in respect of all timber which could be included as forming part of the national resources available in time of need and of a reserve which, given reasonable care and management, will continue to grow and produce more timber. The relative importance of these small woods and scattered trees is not generally appreciated except by the few directly concerned, though the war-time (1942) survey had indicated that they carried something like one-fifth of the total timber volume in the country. The figure for hedgerow and park timber now arrived at for the whole of Great Britain is 807 million cubic feet and that for the small woods 222 million cubic feet, forming 21 and 6 per cent respectively of the total volume of 3,773 million cubic feet (this includes the large woods). Moreover, the average size of the trees in the hedgerows, parks and small woods is appreciably greater than that in the larger woods, this fact being largely ascribable to the concentration of war-time fellings on the larger woods and on the older crops in them.

Of particular interest in the present survey are the methods adopted for collecting the necessary field data and for computing the results with a measure of the probable errors involved. For the hedgerows and parks, the method already established in the 1938 and 1942 surveys was retained. It consisted in the field examination of a strip 44 yards wide, drawn on selected Ordnance Survey quarter sheets on the scale of six inches to a mile. The percentage of sampling is a very low one, one acre in roughly eight thousand, built up of three independent random sets of the Ordnance Survey maps. The standard error, as a percentage of the actual volume, is computed at 8·5 per cent; this is low enough for all practical purposes, though it does not permit of a reliable break-down of the figures into countries and conservancies—thus the standard error for Scotland alone would be 25 per cent.

As might be expected, the five common hedgerow species, oak, elm, ash, beech and sycamore, are found to constitute the bulk of the volume, about four-fifths of the total, oak with 34 per cent and elm with 19 per cent alone contributing half by number of trees and slightly more by volume. The prospects of maintenance of this resource by growth and recruitment are considered. It is thought that there are enough saplings to maintain the numbers of small hedgerow trees, but the distribution of size classes suggests that the volume of larger hedgerow timber is likely to diminish unless further planting (or storing) is carried out.

For the small woods, between one and five acres, the methods are much more closely linked with the survey of the large woods. Small woods were already known to aggregate 187,000 acres, about 5 per cent of the total woodland area. Again a sampling method was adopted, involving the field examination of small woods in the south-western quarter of each of the Ordnance Survey six-inch quarter sheets selected for the hedgerow census, in the same three samples. This worked out at an aggregate 0·92 per cent sample. These woods were classified into the same types as were differentiated for the large woods, and it is assumed that the average stocking per acre for each type is the same for both categories of size. The objections to this assumption—and they may well be viewed as rather serious—are recognized; but the considerable additional work involved in obtaining independent estimates was not felt to be justified. Since the surveys were made, 5 per cent of the area shown as small woods has been lost to other forms of land use, as compared with 2 per cent of the large woods: this reduces the total area to 178,000 acres comprising 71,730 woods fairly equally distributed between 1–2, 2–3, 3–4 and 4–5 acre units. The current annual growth or volume increment of the trees in these woods is estimated at 5 million cubic feet, to be compared with 97 million in the large woods.

It was thought desirable and worth while, in the course of this census, to collect the necessary data for obtaining a rough estimate of the limited volumes of timber standing in the woodlands classified in the main census as simple coppice, scrub, devastated woods and felled woodland. In these types, there were often thinly scattered trees for which no estimate of volume was made at that time. One sample, usually one acre in extent, was measured on each type in each of the quarter-sheet maps used for the hedgerow estimates. The data indicate a total volume of 85·6 million cubic feet, fairly equally divided between the felled and devastated types taken together and the simple coppice taken with the scrub.

* Forestry Commission. Census Report No. 2: Hedgerow and Park Timber and Woods under Five Acres, 1951. Pp. 88+12 plates. (London: H.M.S.O., 1953.) 5s. net.

Summarizing the current growth data for all the timber of Great Britain, the combined census arrives at a figure of 115·5 million cubic feet annually on the growing stock of 3,773 million cubic feet, or 3 per cent. This amount is not, of course, available for immediate use, as apart from amenity considerations, much of it, particularly for the conifers, must be retained in the standing crops to grow to larger size. With the completion of this national inventory Britain moves into line with the still limited number of countries that have reliable statistics for their forest resources. It remains to keep the information up to date by a regular programme of field-work, since adjustment for estimated growth and reported fellings are inadequate for the purpose: this, it is believed, is being done by the Forestry Commission.

CHARACTERISTICS OF THE IONOSPHERE IN GREAT BRITAIN

ONE of the major items in the programme of radio research conducted by the Department of Scientific and Industrial Research during the past twenty-five years has been the development and maintenance of ionospheric recording stations in Great Britain. Following the research work of Sir Edward Appleton and his co-workers at the Cavendish Laboratory, Cambridge, and the Radio Research Substation, near Peterborough, measurements were begun in 1929 at the Radio Research Station, Slough. In the following year a technique for measuring the critical frequency of the *E*-region was developed from experiments carried out between a transmitting station at the National Physical Laboratory, Teddington, and receiving stations at the Radio Research Station, Slough, and the Halley Stewart Laboratory, London. This enabled the present series of ionospheric measurements to begin in January 1931. As the experimental techniques developed and as knowledge of the complexity of the ionosphere increased, the scope and frequency of the measurements have expanded until, at the present time, observations are made every hour and recorded photographically.

An account of this development of the study of the characteristics of the ionosphere in Britain is described in Radio Research Special Report No. 23 of the Department of Scientific and Industrial Research*, which describes the general nature of the results obtained and illustrates the variation in the measured characteristics of the ionosphere during the period 1931–46.

For the past few years the results of such measurements have been compiled in tabular form and either circulated on an exchange basis to other organizations issuing similar information, or distributed to scientific workers and engineers who have a need for such knowledge in connexion with their research or with the various applications of radio transmission. There exists, however, a large quantity of observational material of great geophysical value accumulated in Britain which has hitherto not been available except in limited amounts and on specific request. The present publication is intended to remove this limitation, and to make available to all who are interested the accumulated results of the past work in this field. The complete data are comprised in nearly eight hundred tables of the results of observations made at the Radio Research Station, Slough, during the years 1930–46, and at Burghead, Scotland, during 1941–46. These tables, which are listed in appendixes to the report, reflect the gradual building up of the observational measurements as knowledge of the subject grew and as the experimental techniques available have developed to that of the present type of fully automatic equipment taking photographic records every hour.

Because of the expense, it is not possible to publish the tables in printed form, and arrangements have been made to make photo-copies available. These may be consulted at the Technical Information and Documents Unit of the Department of Scientific and Industrial Research, Cunard Building, 15 Regent Street, London, S.W.1, or by arrangement at the Radio Research Station, Ditton Park, Slough. Each table is on a separate sheet. A minimum of ten consecutive tables on microfilms can be supplied at 3*d*. per table and a microfilm copy of all tables costs £3 3*s*. Enlargements on sheets 9 in. by 7 in. are available at 1*s*. per table. Sets of not less than a hundred consecutive tables can be supplied at £2 10*s*. per hundred net. Requests for copies of the tables, which should quote table numbers, place of observation (that is, Slough or Burghead) and the form in which they are required (that is, microfilms or sheets) should be addressed to H.M. Stationery Office, P.O. Box 569, London, S.E.1.

The published report and the availability of the results in the above manner are likely to be of great value not only to those directly interested in the transmission of radio waves by means of the ionosphere, but also to those engaged in scientific research in related geophysical fields, such as solar phenomena, the upper atmosphere or the earth's magnetic field.

THE EXPRESSIONS 'GOLGI APPARATUS', 'GOLGI BODY' AND 'GOLGI SUBSTANCE'

By DR. JOHN R. BAKER

Department of Zoology, University Museum, Oxford

THERE are certain objects in cells, such as the nucleus, which obviously correspond from cell to cell and for which special names are necessary. The name 'Golgi apparatus' is commonly used with the implication that it refers to homologous bodies that exist in all or nearly all cells of animals. I myself formerly believed that nearly all cells of animals did, in fact, contain such homologous bodies, to which it was appropriate to give a single name.

The so-called Golgi apparatus or Golgi substance is ordinarily identified by its capacity to reduce osmium tetroxide or silver nitrate under certain specified conditions. Now, as I have argued at some length elsewhere[1], the so-called Golgi techniques are not reliable either morphologically or histochemically. They are very liable to give appearances that are misleading from the morphological point of view, because particles of osmium hydroxide or of silver tend to add themselves to one another without regard to pre-existing structure. When granules in the cytoplasm are grouped close together, osmium or silver tends to fill up the spaces between them. Thus a 'network' is produced in the epithelial cells of the mammalian epididymis, though when the so-called Golgi apparatus of these cells is separated by centrifuging it is seen to consist of separate, nearly spherical objects[2]. Similarly, it has recently been shown by Shafiq[3] that there are simple, spherical objects in the cytoplasm of the living nerve-cell of *Locusta* which are transformed by the classical Golgi techniques into the kind of 'Golgi bodies' known as 'platelets', with the characteristic circular or crescentic osmiophil rim.

The Golgi techniques have even less value in histochemistry than in morphology, for all sorts of chemically unrelated substances are capable of reducing osmium tetroxide and silver nitrate. Some of the objects called Golgi bodies are easily stained in life by the mitochondrial vital dyes, but not at all by neutral red or methylene blue; others are stained strongly by the two latter dyes, but not at all by the ones that stain mitochondria; others again cannot be stained by vital dyes of either type. Some take up sudan black in sections made on the freezing microtome, others do not; some can easily be shown by standard mitochondrial methods for paraffin sections, others cannot.

In recent years it has become possible to apply rigorous *in situ* histochemical methods to osmiophil bodies of various kinds[4], and a start has even been made towards their isolation for direct chemical and enzymological analysis[2,5]. May we not take encouragement from these developments, and view the whole subject in a new light? May we not content ourselves by describing how the lipide material is distributed in each particular cell—some of it perhaps as globules of reserve fat (simple triglycerides), some as a component of the mitochondria, and some *in various other forms*, differing widely in shape, composition and significance in different cases? May we not give accepted chemical names as soon as each constituent is identified, instead of using the expression 'Golgi substance', which has no meaning for the biochemist, the very person whose job it is to study the substances that compose the organism?

The massive evidence collected by Hirsch[6] has shown that secretory products of very various kinds arise in connexion with so-called Golgi bodies. Instead of saying that Golgi bodies secrete this or that, may we not say that newly formed secretion-globules often have a lipide-containing sheath around them, and then go on to give the chemical composition (and enzyme content, if any) of the sheath?
